The direct detection of gravitational waves is expected to occur before 2012. This gravitational spectrum will open a new window to studying the universe, comparable to the revolution fathered by the invention of radio astronomy in the 1950s. The direct mapping of the gravity spectrum will broaden our knowledge about the universe, from the earliest moment of the Big Bang to the end of stars.

GROUP VELOCITY

Waves often propagate as a packet, or group, within which there are several wave crests. A common illustration is given by the wave pattern formed when a stone is thrown into a pond. An axially symmetric ring of waves on the water surface propagates outwards as a wave group; within the group, however, one can see that the wave crests propagate through the group, apparently from the rear to the front. The speed of the wave crests, called the *phase velocity*, is different from that of the group as a whole, this speed being called the *group velocity*. For water waves, the phase velocity is greater than the group velocity, except for the very short waves dominated by surface tension.

This important distinction between phase and group velocity arises in all physical systems which support waves. The concept of group velocity appears to have been first formulated by William Hamilton in 1839 (quoted by Havelock, 1914). The first recorded observation of the group velocity of a (water) wave is due to John Scott Russell in 1844 (Russell, 1844) (note also his remark that “the sound of a cannon travels faster than the command to fire it” (Russell, 1885)). However, our present understanding of group velocity is usually

attributed to George Stokes, who used it as the topic of a Smith's Prize examination paper in 1876.

For simplicity, consider a linearized system, with a single spatial variable x and time represented by t . Then a sinusoidal wave has the representation,

$$u(x, t) = a \cos(kx - \omega t + \phi). \quad (1)$$

Here k is the wave number, ω is the wave frequency, a is the constant amplitude, and ϕ is a constant phase. Thus, this sinusoidal wave has a wavelength $\lambda = 2\pi/k$ and a wave period $T = 2\pi/\omega$. Equation (1) is a kinematic expression, valid for all physical systems which support waves. The dynamics of the system are governed by the dispersion relation

$$\omega = \omega(k), \quad (2)$$

defining the frequency as a function of wave number. The phase velocity $c = \omega/k$ is likewise a function of wavenumber.

To obtain the group velocity, consider an argument first advanced by Stokes (1876) and later in more general form by Lord Rayleigh (1881). Form the linear superposition of two sinusoidal waves, each of the form (1) with frequencies $\omega \pm \Omega$, wave numbers $k \pm K$, and with equal amplitudes a and phases ϕ which can be written as

$$u(x, t) = 2a \cos(kx - \omega t + \phi) \cos(Kx - \Omega t). \quad (3)$$

This expression can be viewed as a wave packet, or group, with a dominant wave number k and frequency ω , and with a group velocity of Ω/K . Taking the limit $K \rightarrow 0$, one sees that the group velocity is given by

$$c_g = \frac{d\omega}{dk}, \quad (4)$$

which can be obtained by differentiation of the dispersion relation (2).

A more general argument that links the origin of a wave packet to initial conditions uses Fourier superposition to represent the solution of an initial-value problem in the form

$$u(x, t) = \int_{-\infty}^{\infty} F(k) \exp(i(kx - \omega t)) dk + \text{c.c.}, \quad (5)$$

where $F(k)$ is the Fourier transform of $u(x, 0)$ and c.c. stands for complex conjugate. Thus, the initial conditions determine the Fourier transform, each component of which evolves independently with frequency ω related to the wave number k

through the dispersion relation (2). To obtain a wave packet, we suppose that the initial conditions are such that $F(k)$ has a dominant component centered at $k = k_0$. The dispersion relation is then approximated by

$$\omega = \omega_0 + b_1(k - k_0) + b_2(k - k_0)^2, \quad (6)$$

where

$$b_1 = \frac{d\omega}{dk} = c_g, \quad \text{and} \quad b_2 = \frac{1}{2} \frac{d^2\omega}{dk^2}. \quad (7)$$

Here, both b_1, b_2 are evaluated at $k = k_0$. Expression (5) then becomes

$$u(x, t) \approx A(x, t) \exp(i(k_0 x - \omega_0 t)) + \text{c.c.}, \quad (8)$$

where

$$A(x, t) = \int_{-\infty}^{\infty} F(k_0 + \kappa) \exp[i\kappa(x - c_g t) - ib_2 \kappa^2 t] d\kappa, \quad (9)$$

where the variable of integration has been changed from k to $\kappa = k - k_0$. Here, the sinusoidal factor $\exp(i(k_0 x - \omega_0 t))$ is a carrier wave with a phase velocity ω_0/k_0 , while the (complex) amplitude $A(x, t)$ describes the wave packet. Since the term proportional to κ^2 in the exponent in (9) is a small correction term, it can be seen that to the leading order, the amplitude A propagates with the group velocity c_g , while the aforementioned small correction term gives a dispersive correction term proportional to $t^{-1/2}$. Indeed, it can be shown that as $t \rightarrow \infty$

$$A(x, t)|_{x=c_g t} \sim F(k_0) \left(\frac{2\pi}{|b_2|t} \right)^{1/2} \exp\left(\frac{i\pi}{4} \text{sign } b_2 \right). \quad (10)$$

This same result can be obtained directly from (5) by using the method of stationary phase, valid here in the limit when $t \rightarrow \infty$ (see, for instance, Lighthill, 1978); In this case, it is not necessary to also assume that $F(k)$ is centered at k_0 , and so wave packets are the generic long-time outcome of initial-value problems.

It is useful to note that the group velocity appears naturally in the kinematic theory of waves (Lighthill, 1978; Whitham, 1974). Thus, let the wave field be defined asymptotically by

$$u(x, t) \sim A(x, t) \exp(i\theta(x, t)) + \text{c.c.}, \quad (11)$$

where $A(x, t)$ is the (complex) wave amplitude, and $\theta(x, t)$ is the phase, which is assumed to be rapidly

varying compared with the amplitude. Then it is natural to define the local wave frequency and wave number by

$$\omega = -\frac{\partial \theta}{\partial t}, \quad k = \frac{\partial \theta}{\partial x}. \quad (12)$$

Note that expression (10) has the required form (11). Then cross-differentiation leads to the kinematic equation for the conservation of waves,

$$\frac{\partial k}{\partial t} + \frac{\partial \omega}{\partial x} = 0. \quad (13)$$

But now, if we suppose the dispersion relation (2) holds for the frequency and wave number defined by (12), then we readily obtain

$$\frac{\partial k}{\partial t} + c_g \frac{\partial k}{\partial x} = 0 \quad (14)$$

with a similar equation for the frequency. Thus, both the wave number and frequency propagate with the group velocity, a fact that can also be seen in (10). Equation (14) is itself a simple wave equation, which can be readily integrated by the method of characteristics, or rays. It is important to note that the group velocity c_g is a function of k , so that (14) is a nonlinear equation.

Next, suppose that the physical system contains several spatial variables, represented by the vector $\mathbf{x}$. Then the phase variable $(kx - \omega t)$ in (1, 5) is replaced by $(\mathbf{k} \cdot \mathbf{x} - \omega t)$, where $\mathbf{k}$ is the vector wave number. The dispersion relation (2) is replaced by

$$\omega = \omega(\mathbf{k}). \quad (15)$$

The phase velocity is now a vector ($\mathbf{c}$), has a magnitude $\omega/|\mathbf{k}|$, and is in the direction of $\mathbf{k}$, and the definition of group velocity, replacing (4), is

$$\mathbf{c}_g = \nabla_{\mathbf{k}} \omega. \quad (16)$$

Thus, the group velocity can differ from the phase velocity in both magnitude and direction. A striking example of the latter arises for internal waves, whose group velocity is perpendicular to the phase velocity (see Lighthill, 1978).

Since the group velocity is the velocity of the wave packet as a whole, it is no surprise to find that it can also be identified with energy propagation. Indeed, it can be shown that in most linearized physical systems, an equation of the following form can be derived:

$$\frac{\partial \mathbf{E}}{\partial t} + \nabla \cdot (c_g \mathbf{E}) = 0, \quad (17)$$

where $\mathbf{E}$ is the wave action density, and is proportional to the square of the wave amplitude $|A|^2$, with the factor being a function of the wavenumber $\mathbf{k}$. Typically, the wave action is just the wave energy density divided by the frequency, at least in inertial frames of reference.

So far the discussion has remained within the realm of linearized theory, and it remains to mention the consequences of nonlinearity. Analogous definitions and concepts can be developed, and at least for weakly nonlinear waves, the main outcome is that a dependence on wave amplitude (more strictly, on $|A|^2$) appears in the dispersion relation. This has the consequence that the phase and group velocities both inherit a weak dependence on the wave amplitude. It can be shown that at least within the confines of weakly nonlinear theory, in the case of just a single active spatial dimension, the complex wave amplitude A is governed by the nonlinear Schrödinger (NLS) equation,

$$i \left(\frac{\partial A}{\partial t} + c_g \frac{\partial A}{\partial x} \right) + b_2 \frac{\partial^2 A}{\partial x^2} + \mu |A|^2 A = 0. \quad (18)$$

Here recall that b_2 is defined in (7), and μ is a nonlinear coefficient which is system-dependent.

If A is assumed to depend only on t then Equation (18) has the plane wave solution

$$A = A_0 \exp(i\mu |A_0|^2 t), \quad (19)$$

which shows that the nonlinear coefficient μ has the physical interpretation that $-\mu |A_0|^2$ is the nonlinear correction to the wave frequency. It can be shown that this plane wave is stable (unstable) according as $\mu b_2 < (> 0)$ (see Whitham, 1974). In the unstable case, $\mu b_2 > 0$, a perturbed plane wave will evolve into one or more solitons, where the soliton family is given by (see Zakharov and Shabat, 1972),

$$A(x, t) = \alpha \exp(-i\mu \alpha^2 t) \text{sech}(\gamma \alpha (x - c_g t - x_0)),$$

where $\gamma^2 = \frac{\mu}{b_2}$. (20)

Here, x_0 is a phase constant determining the location of the soliton at $t=0$, and the amplitude α is a free parameter. In linear theory, the wave packet profile is determined by the initial conditions, whereas the influence of even weak nonlinearity, when it is balanced by weak dispersion, results in the generic sech profile.

GROWTH PATTERNS

Patterns are ubiquitous in nature. They can range from the broad stripes on a zebra, to the intricate design of a snowflake, to the rib patterns on a saguaro cactus. The idea that naturally occurring patterns might have some underlying and universal governing mathematical structure has long been a source of fascination to researchers. The study of biological patterns was pioneered by D'Arcy Thompson in his landmark treatise *On Growth and Form* (Thompson, 1942). This was followed by a notable contribution by the mathematician (and Enigma code breaker) Alan Turing in a now famous paper "The Chemical Basis of Morphogenesis" (Turing, 1952). A more contemporary account of many biological patterns and their mathematical modeling is given in James D. Murray's textbook *Mathematical Biology* (Murray, 2003). But to what extent are patterns universal? Are there any connections among the three examples cited above? Inevitably, the underlying physical and biological processes governing a particular pattern-forming process can be very different, even if the topology of the resultant patterns and certain "defects" in those patterns look very similar. In some cases, different governing physical processes end up having essentially the same mathematical formulation, and in these cases, commonality of pattern structure is less surprising.

Here, we will concentrate on two physical pattern-forming systems that are popular topics of contemporary research in condensed-matter physics, namely, the fingering patterns at the interface of fluid mixtures and formation of dendritic crystals in solidification. Some of the patterns seen in these two systems are also seen in growing bacterial colonies.

The Hele-Shaw Cell: Fluid Fingering

This classic problem was first studied at the end of the 19th century, but even to this day there are

Figure 1. Three different types of growth patterns: (a) Hele-Shaw fingers; (b) dendritic crystals; (c) *Bacillus subtilis* bacterial colonies.

still unresolved issues relating to the stability of the patterns exhibited. The experimental setup is relatively simple, consisting merely of a thin film of fluid sandwiched between two glass plates into which air (or another fluid) is pumped. As the air is pumped into the fluid film, one might imagine that it simply forms an expanding circular planar bubble. Initially this appears to be the case, but the circular perimeter rapidly becomes wavy and these "waves" then grow into long finger-like structures which, in turn can split or side branch forming highly complicated patterns. A typical pattern is shown in Figure 1a. The physical principles governing the growing air-fluid interface are well understood. The key idea is that the normal velocity of the air-fluid boundary (i.e., the velocity in the direction normal to each point of the interface) is governed by the gradient of the pressure across the interface. Because the fluid layer is so thin, the equations of fluid mechanics are greatly simplified, and one ends up with governing equations of the form

$$\nabla^2 p = 0, \quad (1)$$

$$u_n = -\frac{b^2}{12\mu}(\nabla p) \cdot \mathbf{n}, \quad (2)$$

$$\Delta p|_{\partial\Omega} = \sigma\kappa. \quad (3)$$

The first equation, in which $p = p(x, y)$ denotes the pressure, is a statement of the incompressibility of the fluid. In the second equation, u_n denotes the normal velocity (in the normal direction $\mathbf{n}$) of the interface. This is determined by the pressure gradient, the thickness of the fluid film b , and the fluid viscosity μ . The third equation describes the pressure jump Δp across the air-fluid interface $\partial\Omega$, and this depends on the surface tension σ and the interface curvature κ (the Young–Laplace law). Unlike more standard systems of partial differential equations in which the equation and boundary conditions are specified, the solution to this problem involves finding the boundary, $\partial\Omega$, itself. This is an example of a Stefan problem. At first sight the equations might look linear, but the coupling to the boundary dynamics makes them effectively highly nonlinear. Finding an exact solution of these equations is very difficult. A standard "linear stability" analysis is relatively straightforward and can explain why the initial circular air-fluid interface becomes

wavy. But beyond this, finding solutions for the finger-like structures, let alone fingers whose tips split, is (still) a difficult problem. A pioneering early study of the Hele-Shaw cell is due to Philip Saffman and Geoffrey Taylor (1958), and many hundreds of papers have been published on the problem in subsequent years.

Solidification and Dendritic Crystal Growth

At first sight this seems like a very different process. Cooling a drop of a molten substance (or a supersaturated salt solution) can produce very striking needle crystals that grow with approximately constant velocity and develop side branches. A typical pattern is shown in Figure 1b. Many questions come to mind: why do finger-like structures form; what determines their propagation speed; why do they form side branches; and is there any connection with the finger-like structures seen in the Hele-Shaw cell? Before addressing these questions it is worth noting that historically the study of dendritic growth had its origins in metallurgical studies associated with the casting of canons. It was discovered that during the casting process the solidifying metal developed a crystalline structure that could weaken the canon—to the point of its shattering when it was fired!

The physical process determining the growth of the solid phase is that of cooling, with the rate of cooling being determined by the rate at which heat can diffuse away from the solid-melt interface. The speed at which the solid front advances is determined by the temperature gradient across the interface. Using these basic principles, the governing equations are found to be

$$\frac{\partial T}{\partial t} = \nabla^2 T, \quad (4)$$

$$u_n = -\alpha(\nabla T) \cdot \mathbf{n}, \quad (5)$$

$$T|_{\partial\Omega} = T_m - \beta\kappa. \quad (6)$$

Here, the first equation is just the diffusion equation for the temperature field T . The second equation for the normal velocity, u_n , of the solidification front is exactly analogous to the one for the Hele-Shaw cell. The third equation expresses the temperature drop at the solid-melt interface $\partial\Omega$ in which the normal melting temperature T_m is corrected by subtle effects related to the curvature of the interface (the Gibbs–Thompson effect). In more sophisticated theories, there is an additional correction proportional to the velocity of the moving front itself. Here, α and β are certain parameters reflecting the physical properties of the crystallizing substance. Thus, despite the very different physics, the mathematical description of the Hele-Shaw cell and a solidifying melt are almost identical Stefan problems. Again, solving the equations is difficult. Apart from a linear stability analysis (leading to the so-called

Mullins–Sekerka instability criterion (Langer 1980)), solutions for the dendritic structures and a description of the side-branching structure in particular are very difficult. A classic review of dendritic growth is Langer (1980) and a more recent textbook is Davis (2001).

Other Pattern-Forming Systems

The formulation of the above problems indicates that two quantities appear to play a key role: the gradient of a field variable (pressure or temperature in the above examples) that drives the evolution of the pattern, and curvature of the interface (Pelcé, 1988; Ben-Jacob & Garik, 1990). In fact, these two quantities also play important roles in other pattern-forming systems. In almost every problem whose pattern is in the form of a propagating front or interface (another classic example is flame propagation), the curvature, and the parameter that multiplies it (e.g., surface tension in the case of the Hele-Shaw cell), plays an important role in determining the basic pattern wavelength.

In the introduction, we cited bacterial colony formation as another example of a pattern-forming system. A typical pattern, of a colony of *Bacillus subtilis* on an agar plate, is shown in Figure 1c. What drives the formation of these patterns? A fundamental concept is that of chemotaxis, namely, the response of the organisms to a concentration gradient. Thus, flux of cells in a medium is typically determined by the nutrient gradient. This principle enables one to write down systems of coupled diffusion and hydrodynamic equations for the concentration of cells responding to the nutrient gradient, and for the nutrient concentration itself, which is clearly going to be depleted in regions of high cell concentration. The ensuing nonlinear feedback between these quantities can lead to a rich, and much-studied, pattern structure (Lega & Passot, 2003).

H

HAMILTONIAN SYSTEMS

A system of $2n$, first order, ordinary differential equations

$$\dot{z} = J \nabla H(z, t), \quad J = \begin{pmatrix} 0 & I \\ -I & 0 \end{pmatrix} \quad (1)$$

is a Hamiltonian system with n degrees of freedom. (When this system is non-autonomous, it has $n + 1/2$ degrees of freedom.) Here H is the Hamiltonian, a smooth scalar function of the extended phase space variables z and time t ; the $2n \times 2n$ matrix J is called the “Poisson matrix”; and I is the $n \times n$ identity matrix. The equations naturally split into two sets of n equations for *canonically conjugate* variables, $z = (q, p)$, as follows.

$$\dot{q} = \partial H / \partial p, \quad \dot{p} = -\partial H / \partial q.$$

Here the n coordinates q represent the configuration variables of the system (positions of the component parts), and their canonically conjugate momenta p represent the impetus associated with movement. These equations generalize Newton’s second law: $F = ma = dp/dt$, to systems (like particles in magnetic fields, or motion in non-inertial reference frames) where the momentum is not simply mass times velocity. The Hamiltonian usually represents the total energy of the system; thus, if $H(q, p)$ does not depend explicitly upon t , then its value is invariant, and Equations (1) are a conservative system. More generally, however, Hamiltonian systems need not be conservative.

William Rowan Hamilton first gave this reformulation of Lagrangian dynamics in 1834 (Hamilton, 1835). However, Hamiltonian dynamics is much more than just a reformulation. It leads, for example, to Henri Poincaré’s geometrical insight that gave rise to symplectic geometry, and it provides a compact notation in which the concept of integrability is most naturally expressed and in which perturbation theory can be efficiently carried out. Moreover, nearly integrable Hamiltonian systems exhibit a remarkable stability expressed by the famous results of Kolmogorov–Arnol’d–Moser (KAM) theory and also Nekhoroshev theory. The Hamiltonian

formulation also provides the foundation of both statistical and quantum mechanics.

Importantly, virtually all of the dynamical laws of physics—from the motion of a point particle to the interaction of complex quantum fields—have a formulation based on Equations (1). For example, frictionless mechanical systems are described by a Hamiltonian $H(q, p) = K(p) + V(q)$, where K is the kinetic energy (which is often quadratic in p) and V is the potential energy. For example, an ideal planar pendulum consists of a point particle of mass m attached to a massless rigid rod of length L whose other end is attached to a frictionless pivot. The most convenient configuration variable for the pendulum is $q = \theta$, the angle of the rod from the vertical. The gravitational potential energy of the system is then $V = -mgL \cos \theta$, and its kinetic energy is $K = p^2 / (2mL^2)$, where p is the angular momentum about the pivot. For this case Equations (1) become

$$\dot{\theta} = \frac{\partial H}{\partial p} = \frac{p}{mL^2}, \quad \dot{p} = -\frac{\partial H}{\partial q} = -mgL \sin \theta. \quad (2)$$

The point $(0, 0)$ is a stable (elliptic) equilibrium corresponding to the pendulum hanging down, at rest. The point $(\pm\pi, 0)$ is also an equilibrium but is an unstable (saddle) point. The unstable eigenvector of the saddle is the beginning of the unstable manifold, W^u , a trajectory that is backwards asymptotic to the saddle. By energy conservation, the unstable manifold corresponds to a branch of the energy contour $E = mgL$, which again joins the saddle point (after the pendulum has undergone one full rotation). Thus, this trajectory is forward asymptotic to the saddle as well; that is, it lies on the stable manifold, W^s , of the saddle. Orbits of this kind are called *homoclinic*. In this case the homoclinic orbit separates the trajectories oscillating about the elliptic equilibrium from those in which the pendulum undergoes complete rotations, thus it is called a *separatrix*. Orbits near the elliptic equilibrium oscillate with the frequency of the linearized, harmonic oscillator, $\omega = \sqrt{g/L}$. The frequency of oscillation decreases monotonically as the amplitude increases, approaching zero logarithmically

at the separatrix. The frequency of rotation of the solution grows again from zero as the energy is further increased.

Canonical Structure

The geometrical structure of Hamiltonian systems arises from the preservation of the loop action, defined by

$$A[\gamma] = \oint_{\gamma} p dq - H dt, \quad (3)$$

where γ is any closed loop in (q, p, t) -space. A consequence of Equations (1) is that if each point on a loop γ_0 is evolved with the flow to obtain a new loop γ_t , then $A[\gamma_0] = A[\gamma_t]$: the loop action is known as the *Poincaré invariant*.

The Hamiltonian form of Equations (1) is not preserved under an arbitrary coordinate transformation (unlike the Euler–Lagrange equations for a Lagrangian system). A canonical transformation $(q, p) \rightarrow (q', p')$ preserves the form of the Equations (1). Canonical transformations can be obtained by requiring that the Poincaré invariant of Equation (3) be the same in the new coordinate system, or locally that

$$(p' dq' - H' dt) - (p dq - H dt) = dF$$

is the total differential of a function F . If F is represented as a function of a selection of half of the variables (q, p) and the complementary half of (q', p') , it is a “generating” function for the canonical transformation. For example, a function $F(q, q', t)$ implicitly generates a canonical transformation through

$$p = -\frac{\partial F}{\partial q}, \quad p' = \frac{\partial F}{\partial q'},$$

$$H'(q', p', t) = H(q, p, t) - \frac{\partial F}{\partial t}. \quad (4)$$

In order that this transformation be well defined, the first equation must be inverted to find $q'(q, p)$; this requires that the matrix $\partial^2 F / \partial q \partial q'$ be nonsingular. An autonomous canonical transformation is also called a *symplectic map*. Canonical transformations are often employed to simplify the equations of motion. For example, Hamilton’s equations are especially simple if the new Hamiltonian is a function of only the momentum variables, $H'(p')$. If we can find a transformation to such a coordinate system then the system is said to be integrable. In general, such transformations do not exist; one of the consequences is chaotic motion.

Integrability

Loosely speaking, a set of differential equations is integrable if it can be explicitly solved for arbitrary

initial conditions (Zakharov, 1991). The explicit solution, when inverted, yields the initial conditions as invariant functions along the orbits of a system—the initial conditions are constants of motion. A Hamiltonian $H(q, p)$ is said to be Liouville integrable if it can be transformed to a canonical coordinate system in which it depends only on new momenta. When the energy surfaces are compact and the new momenta are everywhere independent, Arnol’d showed that it is always possible to choose the momentum variables so that their conjugate configuration variables are periodic angles ranging from 0 to 2π (Arnol’d, 1989). These coordinates are called *action-angle variables*, denoted $(\theta, \mathcal{J})$.

As the Hamiltonian is a function only of the actions, $H(\mathcal{J})$, Equation (1) becomes $\dot{\mathcal{J}} = 0$, and $\dot{\theta} = \Omega(\mathcal{J}) = \partial H / \partial \mathcal{J}$. A system is anharmonic when the frequency vector Ω has a nontrivial dependence on $\mathcal{J}$. Thus, for an integrable system, motion occurs on the n -dimensional tori $\mathcal{J} = \text{constant}$. Orbits helically wind around the torus with frequencies Ω that depend upon the torus chosen. When the frequency is nonresonant (there is no integer vector m for which $m \cdot \Omega = 0$), then the motion is dense on the torus.

Any one degree-of-freedom, autonomous Hamiltonian system is locally integrable. A Hamiltonian with more than one degree of freedom, such as pendulum with an oscillating support, is typically not integrable. Systems that are separable into non-interacting parts are integrable, and there are also a number of classical integrable systems with arbitrarily many degrees of freedom. These include the elliptical billiard, the rigid body in free space, the Neumann problem of the motion of a particle on a sphere in a quadratic potential, the Toda lattice, and the Calogero–Moser lattice (Arnol’d, 1988).

Hamiltonian Chaos

The problem of understanding the motion of a slightly perturbed integrable system originated with the desire to understand the motion of the planets. The Kepler problem corresponding to the gravitational interaction of two spherical bodies is integrable; however, once other effects (such as the mutual forces among planets) are included, there appear to be no general, explicit solutions. Poincaré in particular addressed the question of the stability of the solar system, finally realizing that the convergence of perturbation series for the solutions could not be guaranteed and discovering the phenomenon of transverse homoclinic intersections that is a harbinger of chaos (Poincaré, 1892).

Consider the problem

$$H(\theta, \mathcal{J}) = H_0(\mathcal{J}) + \varepsilon H_1(\theta, \mathcal{J}) + \cdots,$$

where the perturbation H_1 depends periodically on the angles and can be expanded in a Fourier series. When

$\Omega(\mathcal{J})$ is nonresonant, a formal sequence of canonical transformations can be constructed to find a set of coordinates in which H is independent of the angle. The problem is the occurrence of denominators in the coefficients proportional to resonance conditions $m \cdot \Omega(\mathcal{J})$ for integer vectors m . Even for actions where the frequencies are incommensurate, it is always possible to make $m \cdot \Omega(\mathcal{J})$ arbitrarily small by choosing large enough integers m . Thus, a priori bounds on the convergence fail. This is called the *problem of small denominators*.

Chirikov realized that small denominators signal the creation of topologically distinct regions of motion (Chirikov, 1979; MacKay & Meiss, 1987). Near a typical resonance, one can use averaging methods to approximate the motion by an integrable pendulum-like Hamiltonian, effectively discarding all of the terms in H_1 except for those that are commensurate with the resonance, that is, the Fourier modes $H_m(\mathcal{J})$ with $m \cdot \Omega = 0$. Thus, orbits near to a resonance are trapped in an effective potential well. The domain of the trapped motion has the width in action of the corresponding pendulum separatrix; it is typically proportional to the square root of the m th Fourier amplitude of H_1 . If we can treat the resonances independently, then each gives rise to a corresponding separatrix. However, as the perturbation amplitude grows, this approximation must break down as it predicts the overlap of neighboring separatrices. In 1959, Chirikov proposed this resonance overlap condition as an estimate of the onset of global chaos. Renormalization theory gives a more precise criterion (See **Standard map**).

This picture, together with the fact that rational numbers are dense, leads to the expectation that none of the invariant tori of an integrable system persist when it is perturbed with an arbitrarily small perturbation. Surprisingly, the Fermi–Pasta–Ulam computational experiment in 1955 (Fermi et al., 1965; Weissert, 1997) failed to find this behavior. Indeed, KAM theory, initiated by Andrei Kolmogorov in the 1950s and developed in the 1960s by Vladimir Arnol'd and Jürgen Moser, proves persistence of most of the invariant tori (de la Llave, 2001; Pöschel, 2001). This holds when the perturbation is small enough, provided that the system satisfies an anharmonicity or nondegeneracy condition, it is sufficiently differentiable, and the frequency of the torus is sufficiently irrational. The irrationality condition is that $|m \cdot \Omega| > c/|m|^\tau$ for all nonzero integer vectors m and some $c > 0$ and $\tau \geq 1$; this is a *Diophantine condition*. Each of these conditions is essential, though some systems (such as the solar system for which the frequencies are degenerate) can be reformulated so that KAM theory applies.

Resonant tori and tori whose frequencies are nearly commensurate lie between the Diophantine tori. Generally, these tori are destroyed by a small perturbation and either form new, secondary tori

trapped in a resonance or are replaced by a zone of chaotic motion that is found in the neighborhood of the stable and unstable manifolds of the resonance. These generically intersect and give rise to a homoclinic tangle or trellis that contains a Smale horseshoe. In the case that the Hamiltonian is analytic, the size of the chaotic region is exponentially small in ε and, thus, can be difficult to detect (Gelfreich & Lazutkin, 2001).

For small perturbations of an integrable Hamiltonian, it remains an open problem to show that a nonzero volume of initial conditions behaves chaotically, in the sense that they have positive Lyapunov exponents. Numerical investigations indicate that orbits in the chaotic zones do have positive Lyapunov exponents, and that these domains form a “fat fractal” (a fractal with positive measure). There are also many examples of uniformly hyperbolic dynamics (especially for the case of billiards (Bunimovich, 1989)) which can also have properties such as mixing and ergodicity.

The problem of the nonlinear stability of a typical system is also open (See **Symplectic maps**). However, N.N. Nekhoroshev showed in 1977 that for an analytic system, the actions drift very little for very long times (at most by an amount that is proportional to a power of ε for times that are exponentially long in ε (Lochak, 1993; Pöschel, 1993)). Thus, while it is possible that a KAM torus is unstable, for most practical purposes, they appear to be stable.

Generalizations

Many partial differential equations (PDEs) also have a Hamiltonian structure. For a PDE with independent variables (x, t) , the canonical variables are replaced by fields $(q(x, t), p(x, t))$ and the partial derivatives in (1) by functional or Fréchet derivatives, so that

$$\frac{\partial q}{\partial t} = \frac{\delta H}{\delta p}, \quad \frac{\partial p}{\partial t} = -\frac{\delta H}{\delta q}.$$

The Hamiltonian functional H is the integral of an energy density. For example, the wave equation has the Hamiltonian $H[q, p] = \int dx \frac{1}{2} (p^2 + c^2 (\partial_x q)^2)$. Other nonlinear wave equations such as the integrable nonlinear Schrödinger, Korteweg–de Vries, and sine-Gordon equations also have Hamiltonian formulations.

HARMONIC GENERATION

Harmonic generation is the phenomenon whereby new frequency components of a wave are created upon interaction with a nonlinear medium. The concept of a harmonic frequency is familiar to anyone with a basic knowledge of music: two notes whose frequencies form a ratio of small whole numbers (e.g., 2:1, 3:2, 5:4) produce a sound that is pleasing or “harmonious” compared with two notes with incommensurate frequencies. More generally, any periodic function $f(t+T)=f(t)$ can be written as an infinite Fourier series containing the first harmonic (fundamental frequency) $\omega=2\pi/T$, the second harmonic, and higher harmonic frequencies

$$\omega_m = m\omega:$$

$$f(t) = \sum_{m=-\infty}^{\infty} c_m e^{-i\omega_m t}. \quad (1)$$

The function $f(t)$ could represent the displacement of a guitar string, the amplitude of a wave in the ocean, or the electric field strength of a radio wave or a beam of light. If f satisfies a linear dynamic equation, then the principle of superposition holds, and no energy can be exchanged among the different Fourier coefficients c_m . Under nonlinear dynamics, however, the coefficients c_m are coupled to each other, and energy can be transferred back and forth among them.

Harmonic generation refers to the case in which energy originally at frequency ω generates a new wave component at a harmonic frequency ω_m . A closely related phenomenon is that of parametric amplification, in which a frequency ω_m provides the energy source to amplify a signal at a related frequency $\omega_{m'}$.

In optics, harmonic generation is based upon the nonlinear response of some medium to electromagnetic radiation at optical frequencies. The origin of harmonic generation is related to Theodore Maiman's invention of the ruby laser in 1960. Exploiting the high intensities and the coherency properties of the newly available laser output, in 1961 Peter Franken and his colleagues used the nonlinear polarization response of crystal quartz to produce second-harmonic light at a free-space wavelength of 347 nm from the ruby laser output at 694 nm, marking the birth of nonlinear optics.

By the late 1960s, lithium niobate (LiNbO_3) had emerged as the nonlinear crystal of choice for parametric amplification and harmonic generation. Much of the work taking place in the following decades was dedicated to improving the efficiency of the generation of harmonics, either by finding materials with better properties (higher transparency, stronger nonlinearity, etc.) or by aiding the energy transfer through phase matching the various waves involved in the process. More recently, improvements in material processing have made possible the technique of quasi-phase-matching (QPM), in which better phase matching is achieved through the engineering of a spatial variation of the nonlinear coefficient of the medium. In contrast to previous phase-matching techniques, QPM allows a wide, continuous range of frequencies to be coupled to their harmonics without imposing constraints on the orientation of the crystal; the orientation can then be chosen to maximize the nonlinear coefficient seen by the fundamental frequency and its harmonic as they pass through the crystal.

In optics, harmonic generation is often used to convert energy from one frequency band to another. The generated frequency may be more suitable for telecommunications or spectroscopy, for example, and may be in a region of the electromagnetic spectrum

that is not directly available from high-powered lasers. The generation of a harmonic might also be a way of obtaining a coherent copy of an optical pulse, where the copy can be compressed, broadened, chirped, squeezed, or simply measured to determine the properties of the original pulse. Depending on the type of physical process involved and the particular application considered, one refers to the relevant phenomena as second-harmonic generation, sum- or difference-frequency generation, optical parametric generation, or optical parametric oscillation.

The canonical example for studying harmonic generation is an anharmonic oscillator, which can be taken as a simplified model of coherent light propagating through a nonlinear medium. In optics, the nonlinearity can arise due to the material polarization (electronic response) of the medium, or due to a coupling between the light and lattice vibrations in the medium (optical phonons). Referring to the former phenomenon, the polarization response can be expanded in a power series of the applied field, where the coefficients, the nonlinear susceptibility tensors of the material, can be obtained through quantum-mechanical calculations. In general, the quadratic polarization of a medium will be its leading order nonlinear response unless symmetries of the medium rule it out. In this case, one can then reduce Maxwell's equations to the nonlinear wave equation

$$\frac{\partial^2 E}{\partial z^2} - \frac{n^2}{c^2} \frac{\partial^2 E}{\partial t^2} = \frac{\chi^{(2)}}{c^2} \frac{\partial^2 (E^2)}{\partial t^2}, \quad (2)$$

where n is the refractive index of light in the medium, c is the speed of light, and $E(z, t)$ is the electromagnetic field strength which depends on a longitudinal dimension z and on time t .

The nonlinear susceptibility $\chi^{(2)}$ characterizes the quadratic response of the medium to an incident field, where the linear susceptibility has been included in the definition of the refractive index n . To observe the exchange of energy between two frequencies ω_1 and ω_2 mediated by this nonlinearity, the Fourier expansion of Equation (1) can be augmented as

$$E(z, t) = c_1(z) e^{i\theta_1(z, t)} + c_2(z) e^{i\theta_2(z, t)} + \text{c.c.}, \quad (3)$$

where "c.c." denotes the complex conjugate, $\theta_j(z, t) = k_j z - \omega_j t$ is a rapidly varying optical phase, and $k_j = n\omega_j/c$ is the linear wave number. Under the assumption that the coefficients $c_j(z)$ vary much more slowly in z than the optical phase (slowly varying envelope approximation), substituting Equation (3) into Equation (2) gives

$$2ik_1 c_1'(z) e^{i\theta_1} + 2ik_2 c_2'(z) e^{i\theta_2} + \text{c.c.} = \frac{\chi^{(2)}}{c^2} \frac{\partial^2}{\partial t^2} (E^2), \quad (4)$$

where

$$E^2 = c_1^2 e^{i(2\theta_1)} + c_2^2 e^{i(2\theta_2)} + 2c_1^* c_2 e^{i(-\theta_1 + \theta_2)} + 2c_1 c_2^* e^{i(\theta_1 + \theta_2)} + |c_1|^2 + |c_2|^2 + \text{c.c.} \quad (5)$$

In order for the terms on the right of Equation (4) to contribute significantly to the growth of $c_1(z)$ or $c_2(z)$ on the left, the rapid phase rotations given by the exponentials must resonate, which occurs if $\theta_2 = 2\theta_1$, or $\omega_2 = 2\omega_1$. The resulting equations will then be

$$c_1'(z) = \frac{i\omega_1 \chi^{(2)}}{n_1 c} c_1^* c_2 e^{i\Delta k z}, \quad (6a)$$

$$c_2'(z) = \frac{i\omega_2 \chi^{(2)}}{n_2 c} c_1^2 e^{-i\Delta k z}. \quad (6b)$$

The phase mismatch term $\Delta k = k_1 - 2k_2$ arises from a more careful calculation that takes into account that the medium's linear susceptibility (and therefore the refractive index n) is a function of frequency ω ; thus, it is not generally true that $\omega_2 = 2\omega_1$ implies $k_2 = 2k_1$.

Equations (6) can be solved exactly, but it is more instructive to consider the quantities that are invariant in this system of equations. These invariants reflect physical quantities that are conserved during the mixing process (called Manley-Rowe invariants):

$$I_0 = \frac{1}{2} \epsilon_0 c (n_1 |c_1|^2 + n_2 |c_2|^2), \quad (7a)$$

$$I_1 = \frac{1}{2} \epsilon_0 c \left(\frac{n_1 |c_1|^2}{\hbar \omega_1} + 2 \frac{n_2 |c_2|^2}{\hbar \omega_2} \right). \quad (7b)$$

The first of these, I_0 , is the total irradiance, or incident optical power per unit of surface area. That I_0 is invariant follows from conservation of energy, which is to be expected given that no absorption has been accounted for here in the linear susceptibility. The quantity I_1 sums the irradiance from the two frequencies, dividing each by the energy of a single photon at the respective frequency ($E_j = \hbar \omega_j$) before summing. The invariance of I_2 , therefore, reflects a law of conservation of photon flux, as the destruction of two photons at the fundamental frequency ω_1 must bring about the creation of a single photon at the second harmonic, $\omega_2 = 2\omega_1$.

In the spectroscopy of molecular crystals, the fundamental frequency of a vibrating mode sometimes lies close to an overtone or combination of other mode frequencies, whereupon both frequencies are pushed away from each another. In such a case, the overtone or combination band borrows intensity

from the fundamental in a phenomenon called Fermi resonance.

HARTREE APPROXIMATION

In the quantum-mechanical treatment of a system with many degrees of freedom, the Hartree approximation writes the multidimensional correlated wave function as a simple product of one-dimensional or low-dimensional (orbital) functions. This ansatz reduces the full Schrödinger equation to a set of simpler equations for the orbital functions. The Hartree product approximation, first proposed by Douglas R. Hartree (1928) for many-electron atoms, can in principle be applied to any many-particle system, for example, electrons in an atom, molecule, or crystal. However, the Hartree ansatz is often physically inadequate as it disregards the fundamental permutation symmetry requirements for wave functions of nondistinguishable particles (fermions or bosons). In the case of electron systems, the Hartree approximation soon gave way to the more appropriate Hartree–Fock (HF) approximation that is based on a fully antisymmetrized product representation (Slater determinant) of the many-electron wave function proposed by Vladimir A. Fock (Fock, 1930a). For systems with distinct degrees of freedom, on the other hand, such as the multimode nuclear dynamics in molecules, the Hartree product representation still represents a basic approximation. (see, e.g., Beck et al., 2000).

For the many-electron system of an atom or molecule, the (nonrelativistic) stationary Schrödinger

equation can be written in the form (see, e.g., Landau & Lifshitz, 1977)

$$\hat{H} \Phi_n = E_n \Phi_n, \quad (1)$$

where the Hamiltonian $\hat{H} = \hat{H}_0 + \hat{V}$ consists of a one-particle part,

$$\hat{H}_0 = \sum_i \hat{h}_i, \quad \hat{h}_i = -\frac{\hbar^2}{2m} \nabla^2 - \sum_\alpha \frac{Z_\alpha e^2}{|\mathbf{R}_\alpha - \mathbf{r}_i|} \quad (2)$$

i.e., $\hat{H}_0$ is the sum of the Hamiltonians $\hat{h}_i$ associated with the motion of the i th electron in the field of the nuclei with charges eZ_α at positions $\mathbf{R}_\alpha$, and a two-particle part,

$$\hat{V} = \frac{1}{2} \sum_{i \neq j} \frac{e^2}{|\mathbf{r}_i - \mathbf{r}_j|} \quad (3)$$

corresponding to the Coulomb repulsion of the electrons. The complexity of the many-electron problem is due to the latter part of the Hamiltonian, as it prevents a separation of the N -electron Schrödinger equation into N independent single-particle equations. The idea underlying the Hartree and the Hartree–Fock approximation is to replace the full electron–electron interaction by a new approximately separable effective Coulomb repulsion (or “mean field”). In the Hartree case, the optimal mean-field formulation is obtained by making use of a variational principle (Fock, 1930b),

$$\delta \langle \Phi | \hat{H} | \Phi \rangle = 0 \quad (4)$$

with the trial wave function given by a Hartree product

$$\Phi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) = \phi_1(\mathbf{x}_1) \phi_2(\mathbf{x}_2) \dots \phi_N(\mathbf{x}_N) \quad (5)$$

of normalized single-electron functions (orbitals) $\phi_i(\mathbf{x}_i)$. Here $\mathbf{x}_i = (\mathbf{r}_i, s_i)$ comprises in a short-hand notation the set of spatial and spin variables of the i th electron. The resulting equations for the orbitals read

$$(\hat{h} + \hat{v}_k^H) \phi_k(\mathbf{x}) = \varepsilon_k \phi_k(\mathbf{x}), \quad k = 1, 2, \dots, N, \quad (6)$$

where for each orbital $\phi_k(\mathbf{x})$ a distinct mean field

$$\hat{v}_k^H = \sum_{l \neq k} \hat{J}_l, \quad \hat{J}_l = e^2 \int \frac{|\psi_l(\mathbf{r}')|^2}{|\mathbf{r}' - \mathbf{r}|} d\mathbf{r}' \quad (7)$$

augments the one-particle Hamiltonian $\hat{h}$. The physical meaning of $\hat{v}_k^H$ is the Coulomb energy arising from the interaction of the electron in orbital $\phi_k(\mathbf{x})$ and the charge distribution associated with the other orbitals (the operators $\hat{J}_l$ are referred to as Coulomb operators).

Equations (6) are a set of nonlinear integro-differential equations in the orbitals $\phi_1(\mathbf{x}_1)$, $\phi_2(\mathbf{x}_2)$, $\dots$, $\phi_N(\mathbf{x}_N)$. Starting with an initial guess for the orbitals $\phi_k(\mathbf{x})$, these equations have to be solved in

an iterative way until self-consistency is reached. Here it is essential to select appropriate orbital solutions of the individual one-particle eigenvalue problems (6) so that in the N -electron product wave function the Pauli exclusion principle is at least approximately fulfilled. The resulting potential energy operators (7) constitute the Hartree self-consistent field (SCF).

In the many-electron problem, the Hartree approximation is only of historical or pedagogical interest. It was soon succeeded by the more rigorous and practical Hartree-Fock (HF) approximation (Fock, 1930a) based on the proper antisymmetrized product (Slater determinant) representation

$$\Phi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) = \begin{vmatrix} \phi_1(\mathbf{x}_1) & \phi_1(\mathbf{x}_2) \dots & \phi_1(\mathbf{x}_N) \\ \phi_2(\mathbf{x}_1) & \phi_2(\mathbf{x}_2) \dots & \phi_2(\mathbf{x}_N) \\ \vdots & \vdots & \vdots \\ \phi_N(\mathbf{x}_1) & \phi_N(\mathbf{x}_2) \dots & \phi_N(\mathbf{x}_N) \end{vmatrix} \quad (8)$$

of the N -electron wave function. This leads to one common eigenvalue problem for the HF orbitals,

$$(\hat{h} + \hat{v}^{\text{HF}})\phi_k(\mathbf{x}) = \varepsilon_k \phi_k(\mathbf{x}), \quad k = 1, 2, \dots, N, \quad (9)$$

where the HF mean field operator

$$\hat{v}^{\text{HF}} = \sum_{l=1}^N (\hat{J}_l - \hat{K}_l) \quad (10)$$

now contains in addition to the Coulomb contributions a so-called exchange part $-\sum_{l=1}^N \hat{K}_l$, and the nonlocal exchange operators $\hat{K}_l$ are defined by

$$\hat{K}_l \phi(\mathbf{x}) = e^2 \int \frac{\phi_l^*(\mathbf{x}') \phi(\mathbf{x}') d\mathbf{x}'}{|\mathbf{r}' - \mathbf{r}|} \phi_l(\mathbf{x}). \quad (11)$$

Here the integration sums over the spin variable. The HF eigenvalue equation (9) represents a nonlinear problem that again has to be solved in a self-consistent way. It should be noted that because of $(\hat{J}_l - \hat{K}_l)\phi_l = 0$, there arise no self-interaction contributions in the self-consistent HF mean field. Usually, the HF or "molecular" orbitals (MO) are written as linear combinations (LC) of basis functions or "atomic" orbitals (AO). This LCAO representation transforms the integro-differential HF equation (9) into an algebraic eigenvalue problem, and the self-consistency solution is achieved by successive matrix diagonalization. Both with respect to practical applicability and theoretical significance, the HF (or SCF) method is fundamental for electronic structure computations in atoms, molecules, and the solid state. In the LCAO form it is a main ingredient in all existing quantum chemistry program packages. Most of the methods aiming at the description of electron correlation, that is, the effects beyond the HF one-particle picture, are based on the SCF orbital energies and integrals as input data.

Although in electronic structure calculations the Hartree approximation is no longer used, it is still a viable means in the description of nuclear dynamics, that is, the nuclear motion accompanying electronic states and processes. Because one deals here with distinguishable "particles" and not with fermions, the Hartree and not the Hartree-Fock approximation is the appropriate choice. Here one assumes a specific kind of separation of the nuclear and electronic degrees of freedom that has its physical foundation on the large mass differences of electrons and nuclei and correspondingly large differences in the respective velocities (Born & Oppenheimer, 1927). Setting molecular rotations aside, one may write the total wave function as a product of an electronic wave function $\Phi(\mathbf{x}; \mathbf{R})$ and a wave function $\chi(\mathbf{R})$ associated with the vibrational motion of the nuclei:

$$\Psi(\mathbf{x}, \mathbf{R}) = \Phi(\mathbf{x}; \mathbf{R}) \chi(\mathbf{R}) \quad (12)$$

Here $\mathbf{x}$ and $\mathbf{R}$ denote collectively the electronic and nuclear variables. The electronic function is an eigenfunction of the electronic Hamiltonian at spatially fixed nuclei and, thus, depends parametrically on the nuclear coordinates $\mathbf{R}_\alpha$. The product approximation (12) is referred to as Born-Oppenheimer approximation. Having determined the electronic wave function and energy $E(\mathbf{R})$, the Schrödinger equation for the vibrational wave function can be formulated as follows:

$$\left(\sum_{\alpha} -\frac{\hbar^2}{2M_{\alpha}} \nabla_{\alpha}^2 + \hat{U}(\mathbf{R}) \right) \chi(\mathbf{R}) = E_{\text{tot}} \chi(\mathbf{R}) \quad (13)$$

Here the potential energy term $\hat{U}(\mathbf{R})$ is the sum of the nuclear repulsion energy and the electronic energy $E(\mathbf{R})$. Since we are here not interested in translational or rotational motion of the molecule as a whole, it is advantageous to replace the Cartesian coordinates used so far by a set of $M = 3N - 6$ nuclear coordinates $Q_1, Q_2, \dots, Q_M$ describing, for example, the displacements from a reference nuclear configuration. Assuming a separable form of the kinetic energy in the new variables Q_i , that is,

$$\hat{T} = \sum_{i=1}^M \hat{t}_i \quad (14)$$

the Hartree ansatz

$$\chi(Q_1, Q_2, \dots, Q_M) = \chi_1(Q_1) \chi_2(Q_2) \dots \chi_M(Q_M) \quad (15)$$

leads to the following M nonlinear coupled one-dimensional eigenvalue equations,

$$(\hat{t}_i + \hat{u}_i) \chi_i(Q_i) = e_i \chi_i(Q_i), \quad i = 1, \dots, M, \quad (16)$$

where the Hartree mean fields $\hat{u}_i$ are given by

$$\hat{u}_i = \int U(Q_1, Q_1, \dots, Q_M) \prod_{j \neq i} (|\chi(Q_j)|^2 dQ_j). \quad (17)$$

The Hartree product representation is particularly useful in the context of time-dependent methods which solve the time-dependent Schrödinger equation by propagating an initial wave function numerically over a sufficiently long period of time. A very efficient and accurate example of such methods is the multi-configuration time-dependent Hartree (MCTDH) method (Beck et al., 2000). Here the representation of the wave function is given by a linear combination of several Hartree products.

HEAT CONDUCTION

There are two main aspects of the theory of heat conduction that are intensively treated in nonlinear science. The first is related to the possibility of nonlinear terms in the phenomenological equations of heat conduction. The second aspect is related to the microscopic nature of heat conduction and especially to deriving Fourier's law (proportionality of heat flux to the temperature gradient) from the fundamental laws of motion at an atomic level.

Equations of Heat Conduction

In the phenomenological theory of heat conduction, the nonlinearity is normally manifested in temperature dependence of the thermal conductivity coefficient (or concentration dependence of the diffusion coefficient in the related diffusion problem). Such dependence leads to a nonlinear modification of Fourier's law. In the one-

dimensional case, this equation may be written as

$$\frac{\partial T}{\partial t} = \frac{\partial}{\partial x} \left[\kappa(T) \frac{\partial T}{\partial x} \right], \quad (1)$$

where $T(x, t)$ is the temperature field, $\kappa(T) = \vartheta / \rho C$, ϑ is the heat conductivity coefficient, ρ is the density, and C is the heat capacity of the specimen. All parameters introduced above may be significantly temperature-dependent.

As an example of nonlinear heat conduction, consider heat transfer in a hot plasma driven primarily by radiation. The internal energy of the photon gas is $(4\sigma/c)T^4$, where c is the velocity of light and σ is the Stefan–Boltzmann constant. The heat capacity $C = 16\sigma T^3/3c$. Using results of kinetic theory and plasma physics,

$$\lambda \sim T^{7/2} \rho^{-2}, \quad (2)$$

where λ is the mean free path one can derive the final temperature dependence of the thermal conductivity coefficient: $\kappa(T) \sim T^{13/2}$. In the more common case of molecular heat conduction, the transfer is realized by gas molecules, and therefore, the average velocity of the molecules $v \sim T^{1/2}$ and λ is independent of the temperature ($\lambda \sim 1/\rho$); accordingly, the heat conductivity $\kappa \sim T^{1/2}$. More general models deal with the general form of the temperature dependence, like $\kappa = \kappa_0 T^\nu$, $\nu > 0$.

Probably, the most impressive consequence of the temperature dependence of the thermal conductivity coefficient is the phenomenon of so-called “heat inertia” when the heat energy remains localized in the system and does not dissipate away. If $T(x, t)$ is the solution of the Cauchy problem for Equation (1) with initial temperature

$$T(x, t_0) = \begin{cases} T_m(1 - |x|/x_0)^{2/\nu}, & |x| \leq x_0, \\ 0, & |x| \geq 0, \end{cases}$$

then $T(x, t) = 0$ for $|x| \geq x_0$, $t_0 < t < t_0 + t^*$, $t^* = x_0^2 \nu / 2\kappa_0(\nu + 2)T_m^{1-\nu}$; that is, the heat energy is localized in the initial region for a certain time interval.

Microscopic Nature of Heat Conduction

The problem of heat conduction in dielectric crystals goes back to Rudolph Peierls (1926). A linear model of the crystalline lattice, being useful in many other physical problems, turns out to be insufficient when explaining the finiteness of the coefficient of thermal conductivity. The normal process of the heat conduction implies formation of a linear temperature gradient as the temperatures of the boundaries of the specimen are different. In an ideal linear crystal, however, any excitation is presented as a sum of independent vibrational modes that transfer energy from one boundary to the other without any loss. Therefore, a

temperature gradient cannot be formed. This is why an account of the nonlinearity of interactions is necessary to describe the finite heat conductivity. Peierls has suggested that this condition is also a sufficient one because the phonon collision in a weakly nonlinear crystal is governed by the following relationships:

$$\begin{aligned}\omega_1 + \omega_2 &= \omega'_1 + \omega'_2, \\ k_1 + k_2 &= k'_1 + k'_2 + mp.\end{aligned}\quad (3)$$

The values with a prime correspond to the state after collision. The relationship for frequencies ω_i expresses the energy conservation. However the conservation of the quasimomentum k_i can be violated by a multiple of Bragg vector p . The processes with $m = 0$ are referred to as normal phonon scattering. The case with $m \neq 0$ is referred to as Umklapp process. The latter case means that a certain quantity of the quasimomentum is transferred to the lattice. According to Peierls, the fact that the heat flux is scattered due to the Umklapp processes leads to normal heat conductivity. This picture was accepted until Fermi, Pasta, and Ulam examined it in one of the first computer simulations ever accomplished, finding that a one-dimensional chain with weak anharmonicity of the interaction potential did not demonstrate normal heat conduction (See **Fermi–Pasta–Ulam oscillator chain**). Instead, the energy was preserved in a few low-frequency vibrational modes. This famous numerical experiment led to great progress in nonlinear dynamics, including the discovery of lattice solitons, but the problem of the finite heat conductivity of a dielectric crystal again turned out to be unsolved.

It is easy to understand the essence of the problem of finding a sufficient condition for normal heat conductivity. Let us consider a set of equivalent particles arranged along a straight line and interacting only via purely elastic collisions. In every collision the interacting particles mutually exchange their velocities. Any pulse propagates through the system without loss, and therefore, a temperature profile is not formed. Similar properties were proved for the chain with exponential potential of interaction between the nearest neighbors (the so-called Toda lattice).

This problem remains unsolved to date despite numerous efforts. The lack of reliable analytical methods has resulted in many numerical simulations dealing with various lattice models. For one-dimensional systems the results available may be summarized as follows.

- A narrow class of completely integrable systems demonstrates no formation of linear temperature profile at all. Consequently, the coefficient of thermal conductivity cannot be defined. Examples are the linear chain and the Toda lattice.
- For many non-integrable chains, a linear temperature profile is formed and the coefficient of thermal

conductivity may be defined for any given size N of the specimen. However, in the thermodynamic limit $N \rightarrow \infty$, the coefficient diverges: $\kappa \rightarrow \infty$. Therefore, such systems cannot be treated as having normal heat conductivity. Examples are the chain with parabolic and quartic potential among many others.

- A few one-dimensional chains were recently demonstrated to have normal heat conductivity. These examples are the chain of rotators, the Frenkel–Kontorova chain, and some other models.

It should be mentioned that some chains seem to “switch” between different types of behavior with respect to normal heat conductivity with changes of temperature and/or parameters of the potential of interaction.

It seems that different regimes of heat conduction in one-dimensional systems are related to the properties of nonlinear excitations in every concrete model. For instance, the normal heat conduction in the chain of rotators was found to be related to the breakdown of nonlinear acoustic waves and formation of localized breathers, which scatter the heat flux. Similar mechanisms were discovered in other models exhibiting normal heat conduction.

For two-dimensional systems very little information is available, but some investigations suggest that the heat conductivity for different types of potentials is finite or logarithmically divergent. No classification similar to the one-dimensional case can yet be provided.

For the three-dimensional case the situation is as unknown, but the field of molecular dynamics is developing very rapidly and new results are expected to arrive soon.

HEAVISIDE STEP FUNCTION

See **Generalized functions**

HELE-SHAW CELL

A very simple device invented by Henry Selby Hele-Shaw in the late 1890s, the Hele-Shaw cell consists of two closely spaced parallel plates, held in place by a frame, between which is a layer of a viscous liquid. Hele-Shaw invented this simple instrument in order to be able to exhibit the streamlines of a flow to students at University College of Liverpool by projecting the flow in the thin liquid layer onto a large screen. He found that minute air bubbles provided excellent flow tracers, and developed the technique to be able to display in a spectacular manner the flow patterns past a variety of objects.

Hele-Shaw discovered that when the distance between the two plates was very small (he used water as the fluid, and glass plates mounted within 0.02 in. of each other), the flow pattern around a circular cylinder perpendicular to the plates closely matched the potential flow solution that was known from the theory of two-dimensional flow of an ideal fluid. Apparently, the viscous liquid between the plates was flowing in this narrow space as though it were an inviscid fluid. George Stokes explained these observations by writing the equation of motion for a viscous fluid—today known as the Navier–Stokes equation—and averaging the flow (today known as plane Poiseuille flow) across the narrow gap between the two bounding plates in the Hele-Shaw cell. One then finds that the averaged, essentially two-dimensional flow velocity, v , is proportional to the gradient of the pressure, p , in the fluid:

$$v = -(d^2/12\mu)\nabla p, \quad (1)$$

where d is the separation between the plates and μ is the viscosity of the fluid. Thus, flow in a Hele-Shaw cell is potential flow, with a velocity potential proportional to the pressure, and this explains the coincidence between Hele-Shaw's observations and the theory of two-dimensional, ideal flow. As Stokes wrote, "[Hele-Shaw's experiments] afford a complete graphical solution, experimentally obtained, of a problem which from its complexity baffles mathematicians except in a few simple cases."

Hele-Shaw flows illustrate two-dimensional potential flow around objects with sharp edges and thus show no separation. This is quite remarkable, because even the slightest viscosity would immediately alter the flow

Figure 1. Viscous fingering patterns in a Hele-Shaw cell at a gravitationally unstable interface between two immiscible fluids—viscous silicone oil and air. pattern were the fluid not constrained by the two plates of the Hele-Shaw cell.

A controversy with Osborne Reynolds ensued about the validity of the experiments since they appeared to invalidate Reynolds' criterion of a transition to turbulence based solely on the value of "Reynolds number." This led to several acrimonious exchanges of notes and letters in *Nature* in 1898 and 1899 between Reynolds and Hele-Shaw.

The Hele-Shaw cell has found wide application in later years, after it was realized that Equation (1) has the form of the velocity-pressure relationship one would expect for fluid flow in a porous material obeying Darcy's law. Thus, the Hele-Shaw cell became a paradigmatic instrument for studying flows in porous media, a subject of great interest to petroleum engineering.

When two immiscible fluids of different viscosities are present in a Hele-Shaw cell, a number of interesting phenomena occur. In the late 1950s, Geoffrey Taylor and Philip Saffman explored the evolution of "fingers" when a less viscous fluid (air) was pushed into a more viscous fluid (water, glycerin, or oil) in a Hele-Shaw cell. Similar "fingering" occurs when water is forced into oil-carrying porous rock in secondary oil recovery.

The subject of viscous fingering is similar to other pattern-forming instabilities, dendritic crystal growth in

particular, and has become a much studied experimental system. The experimental data tend to be very visually appealing (Figure 1). Many variations on the basic setup have been explored and a voluminous literature exists. The degree of structure of the two-fluid interface depends sensitively on the ratio of viscosities of the two fluids in the Hele-Shaw cell, and the pattern is sensitive to small perturbations, such as imperfections on either plate or tiny air bubbles resident in the cell.

The scale of the smallest fingers observed in a two-fluid Hele-Shaw experiment is set by the surface tension at the interface between the two immiscible fluids. When the surface tension is very small, apparently fractal patterns emerge.

HELICITY

Intuitively, it is clear that a vortex having a component of velocity along its axis is a helical structure. Many structures fall under this category, including such diverse structures as Taylor–Görtler vortices, leading edge and trailing vortices shed from wings and slender bodies, streamwise vortices in boundary layers and free shear flows, Langmuir circulations in the ocean and analogous structures in the atmosphere, tornados, and rotating storms. Similar structures are observed in space and in laboratory plasmas. Such structures lack reflection symmetry. One of the key quantities characterizing reflection symmetry (or its lack) of a fluid flow is the so-called helicity, which roughly measures how parallel velocity and vorticity are in a fluid flow.

Definition

Helicity $\mathcal{H}_B$ of a solenoidal vector field $\mathbf{B}$ ($\text{div } \mathbf{B} = 0$) in a domain D within any surface S on which $\mathbf{n} \cdot \mathbf{B} = 0$

is defined as the integral

$$\mathcal{H}_B = \int_D \mathbf{A} \cdot \mathbf{B} \, dV \quad (1)$$

with $\mathbf{A}$ being the vector potential of $\mathbf{B}$. Here $\mathbf{B} = \text{curl } \mathbf{A}$ and the quantity $\mathcal{h}_B = \mathbf{A} \cdot \mathbf{B}$ is the helicity density of the field $\mathbf{B}$. Both $\mathcal{H}_B$ and $\mathcal{h}_B$ are pseudoscalars: they change sign under the parity transformation, that is, under change from a right-handed to a left-handed frame of reference. Helicity as defined in Equation (1) is gauge invariant, that is, invariant under replacement of $\mathbf{A}$ by $\mathbf{A} + \text{grad } \phi$, where ϕ is any single-valued scalar field. This type of invariance should not be confused with time invariance of $\mathcal{H}_B$ in a nondissipative medium (see below). It is important that $\mathcal{H}_B$ is gauge invariant only as defined in Equation (1) for volumes bounded by the field surfaces, that is, $\mathbf{n} \cdot \mathbf{B}|_S = 0$. Generalizations of Equation (1) for open field structures (i.e., such that $\mathbf{n} \cdot \mathbf{B}|_S \neq 0$) are not gauge invariant. As a rule these generalizations are also not well-defined topologically. Another generalization is the cross-helicity for two solenoidal fields $\mathbf{B}_1$ and $\mathbf{B}_2$ defined as $\mathcal{H}_{B_1, B_2} = \int_D \mathbf{A}_1 \cdot \mathbf{B}_2 \, dV$. For closed structures, that is, $\mathbf{n} \cdot \mathbf{B}_{1,2}|_S = 0$, cross-helicity is gauge invariant and is symmetric, $\mathcal{H}_{B_1, B_2} = \mathcal{H}_{B_2, B_1}$. Of special interest in physics is a magnetic field, $\mathbf{B}$, in electrically conducting fluids or plasmas (with $\mathcal{H}_B$ termed magnetic helicity) and vorticity $\boldsymbol{\omega}$ in fluid flows with $\mathcal{H}_\omega = \int_D \mathbf{u} \cdot \boldsymbol{\omega} \, dV$ (kinetic helicity), where $\mathbf{u}$ is the velocity and $\boldsymbol{\omega} = \text{curl } \mathbf{u}$.

Geometrical and Topological Meaning

Helicity is important at a fundamental level in relation with the linkage(s) of field lines, such as magnetic lines or vortex lines of fluid flow (see Figure 1). The simplest example of two linked vortex tubes is shown in Figure 1 with fluxes $\Phi_{1,2}$ associated with each tube, that are equal to their circulations $\kappa_{1,2}$. Hence, $\mathcal{H}_B$ is directly related to the most basic topological invariant of two

Figure 1. Prototype configuration of linked field tubes with nonzero helicity (Moffatt & Tsinobor, 1992). Here the field is assumed to be identical to zero except in two closed tubes with axes $C_{1,2}$ and vanishingly small cross section. The field lines are untwisted within each tube, i.e. each line is a closed curve passing once round the tube, and unlinked with its neighbors in the same tube. In such a case $\mathcal{H}_B = \pm 2L_{1,2}F_1F_2$, where $L_{1,2}$ is the linking (or winding) number of the two tubes (in the figure $L_{1,2} = 1$), $F_{1,2}$ are the fluxes (equal to their circulations $\kappa_{1,2}$) associated with each tube, and the + or – sign is chosen depending on whether the linkage is right- or left-handed.

linked curves—their linking (winding) number $L_{1,2}$, which was defined by Gauss in 1833 as

$$L_{12} = L_{21} = \frac{1}{4\pi} \oint_{C_1} \oint_{C_2} \frac{\mathbf{R} \cdot (d\mathbf{x}_1 \times d\mathbf{x}_2)}{R^3}, \quad (2)$$

where $\mathbf{R} = \mathbf{x}_1 - \mathbf{x}_2$, $\mathbf{x}_1 \in C_1$, and $\mathbf{x}_2 \in C_2$. In the general case of an infinite number of field lines, one can approximate the field via a finite number of N of small flux tubes each with flux Φ_i ($i = 1, \dots, N$). Then $\mathcal{H}_B = L_{ij} \Phi_i \Phi_j$, where L_{ij} is the linking number of tubes i and j , and summation is assumed over the repeated indices. In other words, the helicity $\mathcal{H}_B$ can be interpreted as the sum of linking numbers of all pairs of the field lines weighted by the flux. This interpretation remains valid also in the case when the field lines are not closed upon themselves and even may wander chaotically, and the integral of Equation (1) is interpreted as the asymptotic Hopf invariant, that is, asymptotic linking number. The cross-helicity $\mathcal{H}_{B,\omega}$ is interpreted as a measure of mutual linkage of the two fields $\mathbf{B}$ and $\boldsymbol{\omega}$.

Invariance in Nondissipative Media

The magnetic field, $\mathbf{B}$, in a perfectly conducting fluid and vorticity, $\boldsymbol{\omega}$, in an inviscid fluid is governed by the equations

$$\frac{\partial \mathbf{B}}{\partial t} = \text{curl}(\mathbf{u} \times \mathbf{B}), \quad (3)$$

$$\frac{\partial \boldsymbol{\omega}}{\partial t} = \text{curl}(\mathbf{u} \times \boldsymbol{\omega}), \quad (4)$$

describing frozen-field transport of the vector fields $\mathbf{B}$ and $\boldsymbol{\omega}$. Under this nondissipative evolution both the magnetic helicity $\mathcal{H}_B$ and the helicity of vorticity $\mathcal{H}_\omega$ are conserved. Invariance of helicity is directly associated with invariance of the topology of $\mathbf{B}$ and $\boldsymbol{\omega}$.

In cases when the fluid flow is influenced by the presence of the magnetic field, that is, by the Lorentz force (the term $\text{curl}(\mathbf{j} \times \mathbf{B})$ added to the left-hand side of Equation (4)), the helicity of vorticity $\mathcal{H}_\omega$ is not conserved whereas the magnetic helicity remains conserved. Another conserved quantity in this latter case is the cross-helicity $\mathcal{H}_{B,\omega} = \int \mathbf{u} \cdot \mathbf{B} dV$. In principle, one can choose the gauge ϕ in such a way that the helicity density $\mathcal{h}_B = \mathbf{A} \cdot \mathbf{B}$ is a Lagrangian invariant, that is, it is pointwise conserved along the paths of fluid particles and therefore for any fluid volume. Such a choice is possible both for magnetic field and for nonconducting fluid flows.

Dissipative effects (finite electrical resistivity and viscosity) are responsible for the reconnection of field lines and thus for the evolution of helicity. In such a case, helicity is either created or destroyed just as if $\mathbf{n} \cdot \mathbf{B} \neq 0$ on the boundary of the domain.

Kinetic Helicity and Turbulent Dynamo

Helicity plays an important role in the process of growth of magnetic fields in electrically conducting fluids due to fluid motion, called the dynamo process. In turbulent flows with nonzero kinetic helicity, there exists the so-called α -effect, the main ingredient of which is that the large-scale (mean) magnetic field results from currents induced by an electromotive force that is (roughly) proportional to the kinetic helicity $\mathcal{H}_\omega$. An important aspect is that this electromotive force is (generally) nonvanishing for nonvanishing electrical resistivity. There is a buildup of magnetic helicity of the generated large-scale magnetic field, and the importance of finite electrical resistivity is in the dissipation of the small scale (on the energy containing scales of fluid turbulence) magnetic helicity of the opposite sign that allows the build up of the large magnetic helicity (Brandenburg, 2001). Recent laboratory experiments with liquid sodium confirm the possibility of generating a magnetic field by helical fluid flows. The growing magnetic field reacts back on the fluid flow via the Lorentz force that results in a decrease of the electromotive force driving the electrical currents (α -quenching), that is, in a nonlinear saturation in the growth of the mean magnetic field.

Kinetic Helicity and Fluid Turbulence

Present knowledge of the effects of helicity on fluid turbulence is controversial. A difficulty in the assessment of the role of helicity in the dynamics of turbulence stems from the fact that—unlike kinetic energy—helicity is not a positively defined quantity. At a speculative level it is expected that nonvanishing helicity comprises a constraint reducing in some sense the nonlinear processes, and thereby turbulence. The simplest argument is that since $(\mathbf{u} \cdot \boldsymbol{\omega})^2 + (\mathbf{u} \times \boldsymbol{\omega})^2 = \omega^2 \omega^2$, larger $\langle \mathbf{u} \cdot \boldsymbol{\omega} \rangle$ implies reducing of nonlinear processes associated with $\langle |\mathbf{u} \times \boldsymbol{\omega}| \rangle$. Indeed, the so-called Beltrami flows with $\boldsymbol{\omega} = \lambda \mathbf{u}$, possessing in some sense maximal helicity, are linear. However, existing evidence weakly supports the above argument (Moffatt & Tsinober, 1992; Tsinober, 2001). On the other hand, if $\langle \mathbf{u} \cdot \boldsymbol{\omega} \rangle \neq 0$, this is a clear indication of direct and bidirectional coupling of large and small scales. Therefore, in flows with nonzero mean helicity, the coupling between small and large scales is stronger than otherwise. This stronger coupling may aid creation of large scale structures out of small scale turbulence—a process that is frequently called inverse energy cascade. There is little understanding of these processes, although there are suggestions that in the presence of kinetic helicity in compressible fluids there exists an effect ($H\alpha$ -effect) analogous to the above-mentioned α -effect for a magnetic field.

More subtle issues include spontaneous breaking of relexional symmetry and emergence of helicity in initially helicity-free flows. The evidence is based on indications from stability analysis, laboratory observations and quantitative measurements of helicity, and direct numerical simulations of Navier–Stokes equations (Kholmiansky et al., 2001). Finally, kinetic helicity has a considerable effect on the effective diffusivity of a passive scalar that may be enhanced by the presence of helicity by more than a factor of two. In addition, helicity leads to a new “skew-diffusion” effect, that is, appearance of a component of turbulent flux of passive scalar perpendicular to the local mean gradient of a passive scalar.

Applications

In atmospheric physics, the so-called storm-relative environmental (kinetic) helicity (SREH) is routinely used in the U.S. with moderate success as a parameter for characterizing, interpreting, and forecasting tornado and supercell rotating storms (Weisman & Rotunno, 2000). The origin of these structures is not understood, though there are suggestions that the $H\alpha$ -effect (due to the Coriolis force) and intensive heat transport in turbulent convection are among the important physical mechanisms contributing to their formation (Levina et al., 1999). One has to add to this list at least one more factor, the vertical wind shear.

In plasma physics, magnetic helicity plays a central role in magnetic confinement and in the relaxation of plasmas to a minimum-energy state, for example, in toroidal laboratory plasmas and spheromaks. Interestingly, during this process involving reconnection due to small but finite resistivity and turbulence, the total magnetic helicity is approximately conserved and constrains the energy of the magnetized plasma in equilibrium. This minimum energy state is generally a force-free (Beltrami) field, $\text{curl } \mathbf{B} = \lambda \mathbf{B}$ with λ constant.

In astrophysics, magnetic helicity is important in a number of aspects in solar physics (coronal loops, solar wind), the astrophysical dynamo problem (Brown et al., 1999), and cosmology (primordial magnetic field).

HÉNON MAP

By the mid-1970s, examples such as the Lorenz equations had convinced researchers that strange attractors could arise in differential equations modeling physical systems. Unfortunately, the length of time needed to compute solutions coupled with strong contraction rates made it very difficult to observe fractal structures numerically in these examples with the computers then available. The Hénon map provided the first simple equation in which this fractal structure is easily observed.

Michel Hénon’s approach was based on the idea of return maps. The dynamics of differential equations can be modelled by invertible maps, and so evidence of fractal structure in the attractor of an invertible map shows that these objects can exist in differential equations. The Hénon map is a very simple nonlinear difference equation

$$\begin{aligned} x_{n+1} &= y_n + 1 - ax_n^2, \\ y_{n+1} &= bx_n, \end{aligned} \quad (1)$$

where the parameters a and b were chosen as $a = 1.4$ and $b = 0.3$ by Hénon (1976), although other values are also interesting. The attractor, together with some blowups of parts of the attractor, are shown in Figure 1. These pictures are very easy to generate: successive points on an orbit are obtained by evaluating the algebraic expressions on the right-hand side of (1) as the following rough MATLAB program shows:

```
x(1)=0.3; y(1)=0.2;
    % Initial conditions
N=5000;
    % N is the number of iterates
a=1.4;b=0.3;
    % Sets the parameters
for i=1:N
```

Figure 1. (a) Numerically computed attractor of the Hénon map, (1) with $a = 1.4$ and $b = 0.3$; (b), (c), and (d) are blowups of the boxed regions of (a), (b), and (c), respectively, showing the fractal structure of the attractor. Each figure contains the first 5000 points to land in the displayed region.

```

%% Begin the iteration loop here
x(i+1)=y(i)+1-a*x(i)^2;
y(i+1)=b*x(i);
%% That calculated the next
point
end
plot(x,y,'k.')
%% Plot the iterates in the
%% (x,y) plane

```

Despite the simplicity of this program, Hénon used a mainframe (IBM 7040) to perform the 5 million iterates he needed to get a reasonable number of points in the equivalent of Figure 1(d). Figure 1 uses a slightly more sophisticated program to generate the attractor and zoom in on the rectangular regions indicated so that 5000 points can be plotted in each of the blowup regions. This involved 35,724,657 iterations of the map in order to get 5000 points in the smallest blowup region of Figure 1(d). This level of computation would have been almost unthinkable when Hénon wrote his paper.

The Hénon attractor pictured in Figure 1 is computationally cheap, requiring no more than the most simple algebraic operations. Also, the numerical evidence for fractal structure in the attractor is sufficiently convincing that most researchers have come to accept that it is a strange attractor or, at least, to

suspend their disbelief. For this reason it has become a canonical example of chaotic motion. Almost every new technique or relevant theoretical result is applied to the Hénon map as part of the evaluation of the method. Early papers on phase space reconstruction, dimension calculations, chaotic prediction, chaotic control and synchronization, periodic orbit expansions, invariant measure algorithms, etc., have all used the Hénon map as an important test example. Given this general level of acceptance, it may come as a surprise to learn that it is still not known whether there really is a strange attractor for the Hénon map at the standard parameter values ($a = 1.4$, $b = 0.3$).

Hénon (1976) gave a number of reasons for looking at orbits of (1):

- ... we try to find a model problem which is as simple as possible, yet exhibits the same essential properties as the Lorenz system. Our aim is (i) to make the numerical exploration faster and more accurate...;
- (ii) to provide a model which might lend itself more easily to mathematical analysis.

As we have seen, Hénon's aim of making the numerical exploration of apparently chaotic attractors more straightforward succeeded spectacularly. However, he could not have imagined how hard it would be to answer the theoretical questions posed by this deceptively simple map.

Hénon's intuitive explanation for his map in terms of folding, stretching, and contraction is much closer to the formation of horseshoes rather than to the Lorenz model, which has discontinuities in the natural return map. As such, the Hénon map has become a paradigm for the formation of horseshoes as parameters vary (see Devaney & Nitecki, 1979), and it is the more general question of how the attractors of the Hénon map change as the parameters vary that has occupied most theoretical approaches.

By defining a new y variable $y_{\text{new}} = b^{-1}y_{\text{old}}$, Equation (1) can be written in the form of a more general, Hénon-like map:

$$\begin{aligned}x_{n+1} &= -\varepsilon y_n + f_a(x_n), \\ y_{n+1} &= x_n,\end{aligned}\quad (2)$$

where $\varepsilon = -b$ and $f_a(x) = 1 - ax^2$ gives the Hénon map in the new coordinates. This formulation emphasizes the relationship between Hénon-like maps and one-dimensional maps: if $\varepsilon = 0$ then the x equation decouples and x evolves according to the one-dimensional difference equation $x_{n+1} = f_a(x_n)$, which in the original case, (1), is just the standard quadratic family. The Jacobian of the map is ε , so positive ε corresponds to orientation-preserving maps, which is more natural in the context of return maps, although this means that $b < 0$ in Hénon's original formulation, (1). Early efforts toward proving that strange attractors exist in the Hénon map concentrated on extending results for one-dimensional maps to the two-dimensional case with $\varepsilon > 0$ small. On the negative side, Holmes & Whitley (1984) showed that however small ε is, some periodic orbits of the Hénon map appear in a order different from the order in which they appear in the quadratic family. On the positive side, Gambaudo, van Strien, & Tresser (1989) showed that for sufficiently small $\varepsilon > 0$, the first complete period-doubling cascade is associated with the original period two orbit.

The major breakthrough on the existence of strange attractors was made by Benedicks & Carleson (1991). Using delicate mathematical analysis, they were able to show that if $\varepsilon > 0$ is small enough and a is close to $a = -2$ (the equivalent of $\mu = 4$ for the standard formulation of the quadratic map, $\mu x(1-x)$), then there is a positive measure of parameter values for which the Hénon map has a strange attractor. This result was generalized by Mora & Viana (1993) who showed that Hénon-like maps arise naturally near homoclinic bifurcations of maps. It had long been recognized that these bifurcations occur in the Hénon map (see, for example, Holmes & Whitley (1984)), so this made it possible to deduce the existence of strange attractors at values of ε that are not small. Indeed, this important paper provides a method of proving the existence of strange attractors for a set of parameter values with positive measure in a wide variety of

model systems. Despite all these advances, these results only prove that there exist such parameter values and they do not give methods for proving that a strange attractor exists at a *given* parameter value.

Two other avenues of research suggested by the one-dimensional, $\varepsilon = 0$, limit in (2) have led to interesting developments. We have already noted that the one-dimensional order of periodic orbits is not preserved if $\varepsilon > 0$. However, a beautiful theory of partial orders based on period and knot type has emerged, which shows that the existence of some periodic orbits implies the existence of some others in two-dimensional maps (see Boyland (1994) for more details). The second adaptation of one-dimensional approaches is based on the idea of the symbolic dynamics (or *kneading theory*) of unimodal maps. The main idea, introduced by Cvitanovic et al. (1988) and developed by de Carvalho (1999), is to produce symbolic models of the dynamics of the Hénon map by relating the dynamics to modifications of the full horseshoe. This is done by *pruning* the horseshoe, that is, identifying regions of the horseshoe with dynamics that are not present in the Hénon map under consideration and judiciously removing these regions together with their images and preimages, leaving a pruned horseshoe that can still be accurately described.

Much of the current interest in the Hénon map involves the existence and construction of invariant measures for the attractors. This work should lead to a good statistical description of properties of orbits and averages along orbits. So, even now, this simple two-dimensional map with a single nonlinear term is motivating important questions in dynamical systems.

HÉNON-HEILES SYSTEM

Although the molecules of a gas move freely and collide frequently, the stars in a galaxy move under the constraint of long-range interactions and do not collide. The motion of any one star in a galaxy can be modeled as if it moves alone under the constraint of a fixed gravitational galactic potential with cylindrical symmetry. The energy of the star is conserved as is the angular momentum with respect to an axis through the center of the galactic plane and at right angles to it. These two conserved quantities are isolating integrals of the motion. In the absence of a third isolating integral, the distribution of stellar velocities in a galaxy with an axisymmetric potential should be circularly symmetric in the meridian plane, a result contrary to observation (Ollongren, 1965).

The astronomer Michel Hénon and a graduate student Carl Heiles introduced a mathematical model to numerically investigate the third integral problem when Hénon visited Princeton University in 1962. In “order to have more freedom of experimentation” in their numerical studies, they considered the simplified model system, with two degrees of freedom, described by the Hamiltonian (Hénon & Heiles, 1964)

$$H = \frac{1}{2}(\dot{x}^2 + \dot{y}^2) + \frac{1}{2}(x^2 + y^2) + x^2y - \frac{1}{3}y^3,$$

where the last three terms are called V . The choice of coefficients in the cubic potential confers a ternary symmetry on the equipotential lines. The equipotential line for $V = \frac{1}{6}$ is an equilateral triangle, and this is the limiting energy at which the motion is bounded. In the Hénon-Heiles model, the original problem of the third isolating integral is transformed into whether there exists an isolating integral other than the constant energy itself. The Hénon-Heiles Hamiltonian also describes the center of mass reduction of a three-particle periodic chain with linear and quadratic nearest neighbor elastic forces and is, thus, a member of the class of systems investigated in the numerical studies of Fermi, Pasta, and Ulam (Ford, 1992). More generally, the Hénon-Heiles Hamiltonian is one of the simplest non-integrable Hamiltonian systems known. It has become a paradigm for studies of chaos and non-integrability in Hamiltonian systems with two degrees of freedom.

The solutions of the equations of motion corresponding to the Hénon-Heiles Hamiltonian can be repre-

sented by trajectories in the four-dimensional phase space spanned by $(x, \dot{x}, y, \dot{y})$. If the energy is fixed in the range $0 \leq E \leq \frac{1}{6}$ then these trajectories are bounded and recurrent on a three-dimensional energy surface. No techniques are known to construct exact algebraic formulae for the trajectories for arbitrary initial conditions. Approximate solutions can be obtained using perturbation methods or numerical methods. In their numerical studies, Hénon and Heiles plotted the points of intersection between phase-space trajectories and a two-dimensional surface of section in the phase-space. For recurrent trajectories, successive intersection points on the surface of section define an area-preserving two-dimensional discrete time dynamical system or map that shares the important dynamical features of the original system (Poincaré, 1993).

A convenient Poincaré map for the Hénon-Heiles Hamiltonian at fixed energy, in the range $0 \leq E \leq \frac{1}{6}$, is obtained with the surface of section $x = 0$ and $\dot{x} \geq 0$. The coordinate pair $(y, \dot{y})$ in this case uniquely determines an initial point for a trajectory since $\dot{x} = \sqrt{2E - \dot{y}^2 - y^2 + 2y^3/3}$. Thus, the dynamical description is reduced to a study of the Poincaré map from one intersection point $(y_n, \dot{y}_n)$ to the next intersection point $(y_{n+1}, \dot{y}_{n+1})$. The existence of an additional isolating integral in the Hénon-Heiles Hamiltonian would restrict a trajectory to intersect an invariant curve in the surface of section. In the absence of an additional isolating integral, the pattern of intersection points should fill an area on the surface of section. In numerical studies, where the number of intersection points is finite, discrimination between these two signatures is subjective since any finite set of points can be aligned to a smooth curve. Despite this, the interpretation of the intersection points as invariant curves or filled area in the Hénon-Heiles study has been regarded as unambiguous.

Figure 1 shows the intersection points between numerical phase space trajectories and a Poincaré surface of section in the Hénon-Heiles system at four different values of the energy, $E = \frac{1}{24}, \frac{1}{12}, \frac{1}{8}$, and $\frac{1}{6}$.

At $E = \frac{1}{24}$ and $E = \frac{1}{12}$, the intersection points appear to lie on invariant curves. At $E = \frac{1}{8}$, intersection points for some trajectories appear to lie on invariant curves whereas intersection points for other trajectories explore areas on the surface of section. At $E = \frac{1}{6}$, intersection points for most trajectories do not appear to lie on invariant curves (and typically the separation distance between trajectories started from nearby initial conditions diverges exponentially in time, a signature of chaos). A feature that is not revealed in the surface of section portraits at $E = \frac{1}{6}$, but is clear in three-dimensional phase space portraits (Henry & Grindlay, 1994), is intermittency whereby a single trajectory switches in time between regular behavior (close to invariant curves) and irregular behavior (filling areas).

Figure 1. Surface of section portraits for the Hénon–Heiles Hamiltonian at four different values of the energy: (a) $E = 1/24$, (b) $E = 1/12$, (c) $E = 1/8$, (d) $E = 1/6$. The figures on the left are from numerical integrations and the figures on the right are from Birkhoff–Gustavson normal form theory. The figures have been reproduced from Gustavson (1966).

The transition from regular behavior to irregular behavior as the system energy is increased in the Hénon–Heiles model is characteristic of a more general transition from regular behavior to irregular behavior in Hamiltonian systems with two degrees of freedom and in two-dimensional area-preserving maps. A detailed theoretical understanding of this phenomena encompasses collective results from the Birkhoff–Gustavson normal form theory, the Kolmogorov–Arnol’d–Moser (KAM) theory, the Poincaré–Birkhoff theory, the Aubry–Mather theory, the theory of heteroclinic tangles (Poincaré, 1993), and the theory of overlapping resonances (Ford, 1992).

The Birkhoff–Gustavson normal form (Gustavson, 1966) represents the Hamiltonian as an infinite series of harmonic oscillator Hamiltonians through an infinite series of successive canonical transformations. The Hénon–Heiles Hamiltonian is strictly non-integrable at all values of the system energy (Ito, 1985); thus the normal form series for this Hamiltonian does not converge. On the other hand, any finite truncation of the normal form series constitutes an integrable Hamiltonian that can be considered to be “close” in some sense to the Hénon–Heiles Hamiltonian. The additional conserved quantity for an integrable normal

form Hamiltonian can be readily calculated and used to plot the associated invariant curves on the Poincaré surface of section. The KAM theory proves that for a non-integrable Hamiltonian sufficiently close to an integrable Hamiltonian, most of the phase space trajectories are confined to invariant tori, similar to the invariant tori of the integrable system. Thus the surface of section portraits for the Hénon–Heiles Hamiltonian should map out the invariant curves from the truncated normal form Hamiltonian whenever this Hamiltonian is sufficiently close to the Hénon–Heiles Hamiltonian. The difference between the truncated normal form series and the Hénon–Heiles Hamiltonian increases with system energy. This can be seen in Figure 1 where the invariant curves from an eighth order truncation (Gustavson, 1966) are compared side by side with the numerical results for the Hénon–Heiles Hamiltonian.

In Hamiltonian systems with two degrees of freedom, the tori are characterized by a winding number ω_1/ω_2 . The KAM theory proves the existence of invariant tori whose winding numbers are sufficiently irrational that

$$\left| \frac{\omega_1}{\omega_2} - \frac{r}{s} \right| > \frac{k(\varepsilon)}{s^{5/2}}$$

where r and s are co-prime integers and $k(\varepsilon)$ approaches zero as ε approaches zero. Here ε measures the strength of the non-integrable perturbation on the integrable Hamiltonian. The volume of phase-space not filled by invariant tori approaches zero as ε approaches zero. Tori whose winding numbers do not satisfy the stability condition under perturbation breakup according to the Poincaré–Birkhoff theory (rational winding numbers) or the Aubry–Mather theory (irrational winding numbers). The numerical results for the Hénon–Heiles Hamiltonian are consistent with an increasing breakup of tori with increasing energy as less and less tori satisfy the stability criteria.

The motion of an asteroid around the Sun can also be described approximately by a simplified model Hamiltonian with two degrees of freedom. The simplest non-trivial model is a plane circular restricted three-body problem involving the asteroid, the Sun, and Jupiter (Berry, 1978). The two-body motion of the asteroid around the Sun is a Kepler ellipse with frequency ω_A , and the two-body motion of Jupiter about its center of mass with the Sun is taken to be a circle with frequency ω_J . In the restricted three-body problem the effect of the asteroid on the motion of the Sun and Jupiter is neglected, the motion of the asteroid is dominated by the Sun, and the motion of Jupiter is considered to be a perturbation on the motion of the asteroid. The Hamiltonian for this restricted three-body problem is non-integrable, and an application of KAM theory to the problem identifies the frequency ratio ω_A/ω_J with the winding number for invariant tori. Thus, asteroids

should be expected to be found in stable orbits at distances from the Sun where ω_A/ω_J is sufficiently irrational. Indeed, as had been noted by Daniel Kirkwood in 1866, there is an abundance of asteroids at these locations but gaps in the asteroid belt at locations where the frequency ratio is 3:1, 5:2, 7:3, or 2:1; however a detailed understanding of the Kirkwood gaps is still an area of active research (Ferraz-Mello, 1999).

HIERARCHIES OF NONLINEAR SYSTEMS

Although we must deal with many hierarchical structures in the course of life—social, military, and monetary, among others—two are of particular interest

to practitioners of nonlinear science: the biological and cognitive hierarchies.

Biological Hierarchy

It is an empirical fact that living creatures are hierarchical in structure, organized according to a scheme that is roughly as follows.

Biosphere

Species

Organisms

Organs

Cells

Processes of replication

Genetic transcription

Biochemical cycles

Biomolecules

Molecules

Atoms

Several comments are in order. First, it is only the general nature of this hierarchy that is of interest here, not the details. Second, the nonlinear dynamics at each level of description generate emergent structures, and nonlinear interactions among these structures provide a basis for the dynamics at the next higher level (Scott, 2003). Thus, molecules emerge from the nonlinear forces among their constituent atoms, biomolecules emerge from molecules, biochemical cycles (such as the Krebs cycle, which processes energy in a living cell) emerge from interactions among biomolecules, and so on. Third, the emergence of a new dynamic entity usually involves presence of a closed causal loop, which leads to positive feedback and exponential growth that is ultimately limited by nonlinear effects.

Finally, it should be noted that philosophers disagree about the ontological status of an emergent entity. Are the levels mere designations, convenient for academic organization, or do they mark qualitatively different realms of reality?

In attempting to answer this question, it is important to know whether the upper levels of the biological hierarchy can be derived from lower levels, which leads to the concept of reductionism. In other words, can the upper levels of the hierarchy (organisms, species, biosphere) be logically derived from the properties of the lower levels? Or are they in some sense independent? In response to such questions, condensed matter physicist Philip Anderson has commented (Anderson, 1972): “The ability to reduce everything to simple fundamental laws does not imply the ability to start from those laws and reconstruct the universe.”

Why not? Like the flame of a candle, the Belousov–Zhabotinsky reaction, or a nerve impulse, the dynamics of biological systems arise from nonlinear reaction-diffusion processes, in which the particular atoms participating in the reactions change with time. Thus, exact knowledge of the positions and velocities of the

constituent atoms of an organism at one time tells little about the behavior at a later time (Bickhard & Campbell, 2000; Scott, 2002). Of course, a dedicated reductionist would respond that the explanatory net has not been cast far enough—all the atoms and radiation that wander into and out of the organism must be followed—but few seriously propose to do this as it would require computing in detail the dynamics of the entire universe.

Cognitive Hierarchy

Just as the phenomenon of life arises from the hierarchical nature of the biological realm, it has been suggested that the mysteries of mind may stem from an analogous hierarchy, describing levels of activity of the brain. Again ignoring details, this cognitive hierarchy may be sketched as follows.

Human cultures
Phase sequences
Complex assemblies
 ...
Assemblies of assemblies of assemblies
Assemblies of assemblies
Assemblies of neurons
Neurons
Nerve impulses
Nerve membranes
Membrane proteins
Molecules
Atoms

To the previous comments on the biological hierarchy, the following can be added. Although the biological levels are observed—through x-ray diffraction, via electron and light microscopy, or more directly—several levels of the cognitive hierarchy are theoretical constructs. This is particularly so for the cell assemblies and their constituent subassemblies, which Donald Hebb proposed to underlie the dynamic nature of human thought (Hebb, 1949). Thus a particular complex cell assembly that embodies a particular idea (your memory of your grandmother, for example) might involve interactions among several (visual, auditory, conceptual) subassemblies as suggested by Figure 1.

In this figure, the shaded areas do not suggest that all neurons in that region are firing, but only those (perhaps ten thousand or so) that have become specific to this particular memory through many related experiences and interactions. The neurons of this assembly are interconnected in such a manner that they are “capable of interacting briefly as a closed system, delivering facilitation to other such systems and usually having a specific motor facilitation” (Hebb, 1949). As a complex assembly comprises subassemblies that in turn are composed of yet more basic constituent assemblies, the concept is inherently hierarchical.

Figure 1. A sketch of the left side of the human brain, suggesting how the active subassemblies (shaded areas) of a complex cell assembly might be distributed over various lobes of the neocortex.

Although Hebb's theory is in accord with a substantial amount of psychological data (Hebb, 1980; Scott, 2002), it is difficult to imagine placing electrodes in the neocortex so that the simultaneous firings of a substantial number of these assembly neurons could be recorded. Nonetheless, a substantial amount of experimental and numerical data is accumulating in support of this theory.

At higher levels of the cognitive hierarchy, we recognize the phase sequence, in which the focus of thought moves from one complex assembly to the next in a train of thought or a dream. At yet higher levels, important aspects of cultural dynamics—ingrained social prejudices, for example, or an aversion to eating certain foods—may remain unrecognized as they play important roles in human behavior.

HIGGS BOSON

Particle physics is devoted to discovering and investigating the fundamental constituents of all the matter in the universe (at all times), and the forces of nature by which these constituents interact with each other. The theoretical framework that currently aids our understanding is called the Standard Model. Although there is no experimental result that significantly disagrees with the Standard Model, it is not a complete theory; indeed, there are several reasons why the Standard Model is not a theory at all in the normal sense of the word. Perhaps the most important of these is that it contains a large number of parameters (such as the fundamental particle masses) that are not predicted but determined experimentally and then incorporated into the theoretical framework.

A principle mission of particle physics is the development of a complete, fundamental theory that unifies all of the known forces into one. Historically, this process seems to be taking place one pair of forces at a time (for example, James Clerk Maxwell famously unified electricity and magnetism in the 19th century), and an important feature of the Standard Model is that it contains the unification of the short-range weak nuclear force and the long-range electromagnetic force. The strong nuclear force is not yet unified and gravity is completely excluded from the standard model.

Although the successful implementation of electroweak unification encourages particle physicists to consider the Standard Model as a low energy approximation of a more fundamental theory, electroweak unification comes at a price. The quantum of the electromagnetic field is the photon, which has zero rest mass. The weak field has a chargeless quantum, known as the Z particle, and a charged quantum, known as the W particle. The rest masses of the Z and the W are both almost 100 times the proton rest mass. This huge difference in the masses of the particles associated with the electromagnetic and weak force fields is known as electroweak symmetry breaking, and in order to interpret it, physicists have introduced into the Standard Model an arbitrary mathematical trick.

In a series of papers some 40 years ago, Englert and Brout (and independently, Higgs) pointed out that a symmetry-breaking idea used in the theory of superconductivity could also be used to break the electroweak symmetry. This mathematical trick is known in particle physics as the Higgs mechanism. In the theory of superconductivity, the idea explains how photons appear to acquire mass inside a superconductor. Introducing it into the Standard Model provides an explanation of where the Z and W masses come from.

The Higgs mechanism is most readily viewed in terms of a constant, ubiquitous energy field that has no preferred direction in space. This field is known as the Higgs field. It is this Higgs field that breaks

the electroweak symmetry, giving mass to both Z and W while retaining a massless photon. Just as there are well-defined quanta, known as bosons, associated with each of the known force fields, so it is with the hypothetical Higgs field. In the simplest version of the Higgs mechanism, there is just one quantum and it is known as the Higgs particle or Higgs boson.

So, to recap, the Higgs particle is intimately associated with the Higgs field, and the Higgs field is assumed to be responsible for the mass difference between the quanta of the electromagnetic and weak fields. It is not too much of a stretch to expect that the masses of all matter particles (quarks and leptons) somehow get their masses from the Higgs mechanism. Indeed, the coupling of every particle to the Higgs field has strength proportional to its mass, and so this interpretation seems natural. Unfortunately, the Higgs mechanism does not reduce the number of unknown parameters of the Standard Model—there is still one per particle, plus a few more.

Curiously, the assumed Higgs particle has quite well-determined properties. Its mass, like all other particle masses, is not predicted but must be measured. As a function of an assumed mass, however, one can use the Standard Model to calculate the rate at which it will be produced in a high-energy collision of two elementary particles. The Higgs particle is expected to be highly unstable, and it is also straightforward to calculate, using the Standard Model, how it will decay. In other words, what it will decay into and with what relative rates. These Standard Model predictions provide a basis for experimental searches for the Higgs particle.

The particle experimentalists perform experiments in which they collide, at the highest available energy, protons with protons, or protons with antiprotons, or electrons with positrons. They then examine the debris of the collision for evidence of a Higgs particle whose properties match those suggested by the Standard Model.

In this manner, the experimental techniques of particle physics have been able, over the past decade or so, to eliminate the possibility of a Higgs particle with mass below about 120 proton masses or above about 200 proton masses. When the Higgs mechanism was first introduced to particle physics, the mass of the Higgs particle could have been anywhere between zero and about 1000 times the proton mass. One of the remarkable achievements of particle physics over the past few decades has been the elimination of most of this mass region. Of course, this elimination is of a statistical nature and the best thing that physicists can do is to assign a measure of the statistical confidence to these limits. In late 2002, most particle physicists were confident that if the Standard Model Higgs particle exists, its mass is probably in the mass range of approximately 120–200 proton masses (somewhere between the atomic masses of tin

and gold). The Tevatron (proton-antiproton collider accelerator at Fermilab with energy close to 2 TeV) has a chance to investigate the lower 10% of this mass range; the Large Hadron Collider (LHC; proton-proton collider accelerator under construction at CERN with energy 14 TeV, scheduled to start operation in or after 2007) will finish the job. Thus, by 2020 at the latest, we will know whether there is a Higgs particle, and therefore whether Nature uses the Higgs mechanism to generate the masses of fundamental particles.

HIROTA'S METHOD

Ryogo Hirota originally proposed his bilinear method as a "direct method" for constructing multisoliton solutions to integrable equations. The method is "direct" in the sense that one can apply it without resorting to deeper mathematical properties, for example, to those that are needed in order to apply the inverse scattering transform (IST). In practice, this means that Hirota's method is applicable to a wider class of equations. Nevertheless, the bilinear method is related to deep mathematical foundations of soliton theory (Sato theory), as has been shown by the members of the Kyoto school (Sato, Date, Jimbo, Miwa, Kashiwara).

Prototypical Result: The KdV Equation

Let us see how Hirota's bilinear method works for the Korteweg-de Vries (KdV) equation

$$u_{xxx} + 6uu_x + u_t = 0. \quad (1)$$

It is known from IST that multisoliton solutions can be written as $u = 2\partial_x^2 \log(\det M)$, where the entries in M

are of the form $c_0 + c_1 e^{c_2 x + c_3 t}$ for some constants c_i . Thus, $\det M$ is a sum of exponentials and, therefore, an entire function. This inspired Hirota to write the KdV equation in terms of a new dependent variable F defined by (Hirota, 1971)

$$u = 2\partial_x^2 \log F. \quad (2)$$

Then the KdV equation (1) becomes

$$\partial_x [F_{xxx} F - 4F_{xxx} F_x + 3F_{xx}^2 + F_{xt} F - F_x F_t] = 0. \quad (3)$$

Note the derivative outside the brackets, which means that the bilinearization actually works most naturally for the potential KdV equation.

In order to shorten the notation, let us introduce the bilinear derivative operator D as follows:

$$\begin{aligned} D_x^n f \cdot g &= (\partial_{x_1} - \partial_{x_2})^n f(x_1)g(x_2) \Big|_{x_2=x_1=x} \\ &\equiv \partial_\varepsilon^n f(x + \varepsilon)g(x - \varepsilon) \Big|_{\varepsilon=0}. \end{aligned} \quad (4)$$

Then the KdV equation may be written in the simple form

$$(D_x^4 + D_x D_t) F \cdot F = 0. \quad (5)$$

Since F was assumed to be a sum of exponentials, let us try to construct a one-soliton solution (1SS) to (5) using the ansatz

$$F = 1 + e^\eta, \quad \eta = px + \omega t + \eta^0. \quad (6)$$

A direct computation shows that this is indeed a solution, provided that $\omega = -p^3$; this condition on the parameters is called the *dispersion relation*. From (2) we get the usual soliton solution

$$u = \frac{2p^2 e^\eta}{(1 + e^\eta)^2} = \frac{p^2}{2 \cosh^2(\eta/2)}, \quad (7)$$

where $\eta = px - p^3 t + \eta^0$.

A particularly nice feature of the bilinear method is that two-soliton solutions (2SSs) are also very easy to obtain. We assume that a 2SS is constructed from two 1SSs perturbatively as follows:

$$F = 1 + e^{\eta_1} + e^{\eta_2} + a_{12} e^{\eta_1 + \eta_2}, \quad (8)$$

where $\eta_i = p_i x - p_i^3 t + \eta_i^0$.

A direct computation then shows that this is indeed a solution of (5), provided that the *phase factor* is given by

$$a_{12} = \left(\frac{p_1 - p_2}{p_1 + p_2} \right)^2. \quad (9)$$

Using (2) one gets the nonlinear form of the 2SS, which is already rather complicated. The above 1SS and 2SS ansätze actually work (with suitable a_{12}) for any equation having a bilinear form of type $P(D)F \cdot F = 0$, with $P(0) = 0$.

The above can be extended to a 3SS. By considering various asymptotic limits (where one of the three solitons is far away), one finds that the proper ansatz cannot have new free coefficients, but must have the form

$$F = 1 + e^{\eta_1} + e^{\eta_2} + e^{\eta_3} + a_{12}e^{\eta_1+\eta_2} + a_{13}e^{\eta_1+\eta_3} + a_{23}e^{\eta_2+\eta_3} + a_{12}a_{13}a_{23}e^{\eta_1+\eta_2+\eta_3}. \quad (10)$$

In contrast to the 2SS case, this ansatz only works for *integrable* equations of type $P(D)F \cdot F = 0$, for example, the KdV, Sawada-Kotera, and Kadomtsev-Petviashvili equations. In fact, the existence of multisoliton solutions can be used as a criterion of integrability (Hietarinta, 1990).

Examples of Bilinear Equations

Let us next consider the nonlinear Schrödinger equation (NLS)

$$i\phi_t + \phi_{xx} + 2|\phi|^2\phi = 0. \quad (11)$$

It is bilinearized with the substitution

$$\phi = G/F, \quad G \text{ complex, } F \text{ real}, \quad (12)$$

which yields

$$F[(iD_t + D_x^2)G \cdot F] - G[D_x^2 F \cdot F - 2|G|^2] = 0. \quad (13)$$

For normal (bright) solitons we split this into two equations for two functions:

$$\begin{cases} (iD_t + D_x^2)G \cdot F = 0, \\ D_x^2 F \cdot F = 2|G|^2. \end{cases} \quad (14)$$

The 1SS ansatz is given by

$$G = e^\eta, \quad F = 1 + a e^{\eta+\eta^*}, \quad \eta = px + \omega t, \\ p \text{ and } \omega \text{ complex} \quad (15)$$

and from the equations one finds a dispersion relation for the complex parameters, $i\omega + p^2 = 0$, and the value of the phase factor, $a = 1/(p + p^*)^2$.

Hirota's method works also for discrete systems. Consider the (semi-)discrete Toda-lattice equation

$$\ddot{y}_n = e^{-(y_n - y_{n-1})} - e^{-(y_{n+1} - y_n)}. \quad (16)$$

First one goes over to the dependent variable $r_n = y_n - y_{n-1}$, and then the substitution $e^{r_n} = 1 + \partial_t^2 \log f_n$ yields

$$(D_t^2 + 2)f_n \cdot f_n = 2f_{n-1}f_{n+1}. \quad (17)$$

Since $e^{\alpha D_t} f(x) \cdot g(x) = f(x + \alpha)g(x - \alpha)$, we can write (17) also in the form

$$\left[D_t^2 - 4 \sinh^2\left(\frac{1}{2}D_n\right)\right] f_n \cdot f_n = 0. \quad (18)$$

The 1SS is given by

$$f_n(t) = 1 + e^{2(pn + \omega t)}, \quad (19)$$

where $\omega = \pm \sinh(p)$.

The above types of bilinearizations work, *mutatis mutandis*, for several classes of equations, but unfortunately there is no algorithmic method of finding the bilinearizing substitution for a given nonlinear equation. In fact, it is not even clear a priori how many dependent or even independent variables one should use. There are some general guidelines; for example, in order to bilinearize higher members in a hierarchy, one usually needs extra independent variables. If the 1SS and 2SS are known, one may use them in order to make an educated guess about the bilinearizing substitution.

The ultimate bilinear equation, from which many other bilinear equations can be derived as particular limits, is the Hirota-Miwa equation

$$(z_1 e^{D_1} + z_2 e^{D_2} + z_3 e^{D_3}) F \cdot F = 0, \quad (20)$$

where z_i are constants and D_i are arbitrary linear combinations of $D_x, D_y, \dots$

The General Perturbative Approach for Constructing Soliton Solutions

Once a reasonable bilinear form has been found, one can try to find soliton solutions using a perturbative expansion in a fictitious parameter ε (Hirota, 1976):

$$F = f_0 + \varepsilon f_1 + \varepsilon^2 f_2 + \dots, \quad (21)$$

and similarly for the other dependent variables appearing in the bilinear equations. One first chooses a suitable "vacuum" solution (no solitons), that is, constant values for the ε^0 terms, with all other terms vanishing. Next for a 1SS, one uses a minimal nontrivial entry (typically $e^{px+qy+\omega t}$) at order ε , that is, for f_1 , and normally one should then be able to truncate the expansion at this or the next level (cf. (6) or (15)). For a 2SS, the previous 1SS solution is generalized at the ε level by taking the sum of two terms (cf. (8)), and as a result the expansion will truncate later (for KdV at ε^2 , but for NLS we need even powers up to 4 for F and odd powers up to 3 for G). If the expansion does not truncate, it is probable that the equation is non-integrable. What helps here is that since $P(D)e^{a \cdot x} \cdot e^{b \cdot x} = P(a - b)e^{(a+b) \cdot x}$, the highest order terms in $P(D)F \cdot F$ vanish automatically.

In a systematic construction of multisoliton solutions, one uses determinants of Wronskian or Gramian type, or Pfaffians (Nimmo, 1990). Their applicability follows from the fact that determinants often

satisfy quadratic identities, of which the Laplace expansion (a Plücker relation) is a typical example. The type of the matrix used is intimately related to the above-mentioned phase factor of the 2SS.

Bäcklund Transformations

In addition to providing a simple method for constructing multisoliton solutions, Hirota's method is also natural for studying Bäcklund transformations (BTs). In general terms, the starting set of equations and variables is doubled (while adding a new free parameter), and their combination is manipulated in order to get a pair of bilinear equations that are *linear* in each set of variables. Furthermore, if variables of one set are eliminated, one should get back the original equations. For example, the BT of the KdV equation is (Hirota, 1980)

$$\begin{cases} (D_x^3 + 3\lambda D_x + D_t)F' \cdot F = 0, \\ (D_x^2 - \mu D_x - \lambda)F' \cdot F = 0, \end{cases} \quad (22)$$

and if one eliminates F' from this pair, one obtains (a derivative of) (5).

Sato Theory

The reason Hirota's bilinear method works so well is that it is a reflection of an elegant fundamental theory called Sato theory, where bilinear identities (expressed using Young or Maya diagrams) play a major role. The theory naturally yields several infinite hierarchies of equations in an infinite number of variables, and their finite-dimensional reductions are the usual soliton equations. For an introduction, see Ohta et al. (1988) and Miwa et al. (2000).

Because there is so much mathematical structure underlying the bilinear approach, it is not surprising that bilinear forms of various equations have appeared before in the literature (although only in passing). For example, in 1902, Painlevé found bilinear forms for the first three of the six Painlevé equations using a substitution like (2); his idea was to express the equations in terms of entire functions. Indeed, the functions that arise in Sato theory are also entire functions, called τ -functions, and so one often refers to the bilinearizing functions (F and G above, for example) as τ -functions.

Summary

Hirota's bilinear method is a very effective technique in constructing multisoliton solutions. For a given equation, one should first find a one-soliton solution, and using it, one can often guess a method for bilinearizing the nonlinear equation. If that is successful, one can search for multisoliton solutions using the perturbative approach.

It is believed that all integrable evolution equations are obtained as reductions from a limited number of hierarchies, as described in Miwa et al. (2000), although the reductions can be highly nontrivial. Conversely, for a given new integrable equation, one should try to understand its origin as a reduction of one of the known hierarchies, and the bilinear form and the phase factor are helpful in this process.

In practical applications, one must nevertheless be careful, first to avoid bilinearizations that trivialize the system. The usual bilinearizing substitution (2) usually yields a multilinear system. One can forcibly bilinearize it by separating it into smaller bilinear parts and requiring each one of them to vanish independently. But if at the end there are more equations than unknown functions, the set of bilinear equations so obtained may include conditions that did not exist in the original equations.

Also, the existence of a bilinear form does not imply integrability. Bilinear forms have also been written for many non-integrable models, and the existence of a bilinear form does not even imply the existence of N -soliton solutions, nor can one always assume that the bilinearizing functions are τ -functions. Indeed, for a large class of bilinear equations (containing non-integrable equations), it is possible to find two-soliton solutions exhibiting elastic scattering, but that does not imply the existence of a *general* N -soliton solution for any $N > 2$.

HODGKIN-HUXLEY EQUATIONS

Classical experiments on the compound action potential produced by vertebrate nerve trunks provided all the components for a reaction-diffusion model for the propagation of an action potential, with the nerve impulse as a nonlinear traveling wave produced by the nonlinear "reaction" of excitation and the diffusive spread of voltage. Even as late as the 1930s, however, it was not clear if nerve excitation was a membrane phenomenon, or if the extracellular potential changes were a consequence of some chemical excitation propagating through the axoplasm.

The identification of the 100–500 μm diameter giant axons of the squid as single nerve fibers provided a preparation large enough for excitation and propagation in a single nerve fiber to be analyzed in detail. Wires can be inserted down the axoplasm, one to pass current, one to record potential, and one to short circuit the resistance of the intracellular axoplasm, providing a space clamp under which the membrane potential is spatially uniform. Current can be passed between the internal electrode and external electrodes, exciting a membrane action potential that is recorded as the difference in potential V across the membrane.

The membrane current I_m is the sum of a capacitive and an ionic current:

$$I_m = C_m dV/dt + I_{\text{ion}} \quad (1)$$

with the membrane capacitance $C_m = 1 \mu\text{F cm}^{-2}$. Direct recordings of the membrane action potential show that the potential changes sign, from a resting value of -60 mV to a peak value of $+40 \text{ mV}$. The peak of the action potential varies logarithmically with the extracellular Na^+ concentration, showing the role of sodium ion (Na^+) current in the generation of the action potential.

The voltage clamp technique uses a feedback circuit to control the potential across the membrane. Using rectangular command pulses, the membrane potential can be changed from its resting value to an arbitrary value within a fraction of a millisecond. During a voltage clamp, the only current flowing across the membrane is ionic and is equal and opposite to the current that is injected to maintain the clamp. Net ionic currents can be measured, and dissected into their components by ion substitution experiments. From the estimated ionic currents and their electrochemical gradients, the ionic conductances changes can be calculated. Under a depolarizing voltage clamp, the sodium (Na^+)-conductance change is fast and transient, while the potassium (K^+)-conductance change is slower, delayed, and maintained.

Hodgkin & Huxley (1952) fitted their extensive series of experimental measurements of ionic currents obtained under voltage clamp and synthesized their empirical equations into a quantitative model for the propagating action potential.

For axoplasmic resistance R and membrane capacitance C , both per unit length of axon, the spread of membrane potential V with distance x (cm) and time t (ms) is described by a reaction-diffusion equation:

$$C \frac{\partial V}{\partial t} = \frac{1}{R} \frac{\partial^2 V}{\partial x^2} - I_{\text{ion}}, \quad (2)$$

where I_{ion} is a nonlinear function of V and t .

The membrane ionic current I_{ion} is assumed to be composed of three independent components, a Na^+ -current I_{Na} , a K^+ -current I_{K} , and a leakage current density I_{L} ($\mu\text{A cm}^{-2}$) that flow through separate conductance pathways that have different ion-selectivities, maximal conductances, and voltage-dependent kinetics. Thus,

$$I_{\text{ion}} = I_{\text{Na}} + I_{\text{K}} + I_{\text{L}}. \quad (3)$$

The instantaneous current-voltage relation for each pathway is linear, so the current is the product of a conductance and a driving force—the difference between the potential V and the equilibrium (Nernst) potential for the pathway. The Nernst potential is determined by the intracellular (axoplasm) and extracellular (artificial sea water) ionic concentrations, and $V_{\text{Na}} = -115$, $V_{\text{K}} = +12$, and $V_{\text{L}} = -10.613 \text{ mV}$ (the unreasonable precision for V_{L} is to fix $V = 0$ as a stable equilibrium solution). The conductance is the product of the maximal conductance $\bar{g}$ and gating variables—activation m and inactivation h for Na^+ -channels activation n for K^+ -channels. The activation variables are raised to a certain power (3 for m , 4 for n) that empirically reproduces the delayed, sigmoid increase in current and may be interpreted as the number of gating structures per channel. Thus

$$\begin{aligned} I_{\text{Na}} &= \bar{g}_{\text{Na}} m^3 h (V - V_{\text{Na}}), \\ I_{\text{K}} &= \bar{g}_{\text{K}} n^4 (V - V_{\text{K}}), \\ I_{\text{L}} &= \bar{g}_{\text{L}} (V - V_{\text{L}}). \end{aligned} \quad (4)$$

Each gating variable obeys first-order kinetics

$$\begin{aligned} dm/dt &= \alpha_m(1 - m) - \beta_m m, \\ dh/dt &= \alpha_h(1 - h) - \beta_h h, \\ dn/dt &= \alpha_n(1 - n) - \beta_n n \end{aligned} \quad (5)$$

with rate coefficients α and β for opening or closing that are empirical functions of voltage:

$$\begin{aligned} \alpha_n &= \frac{0.01(10 - V)}{\exp(10 - V)/10 - 1}, \\ \beta_n &= 0.125 \exp(-V/80), \\ \alpha_m &= \frac{0.1(25 - V)}{\exp(25 - V)/10 - 1}, \\ \beta_m &= 4 \exp(-V/18), \\ \alpha_h &= 0.07 \exp(-V/20), \\ \beta_h &= \frac{1}{\exp(30 - V)/10 + 1}. \end{aligned} \quad (6)$$

Figure 1. Voltage dependence of time coefficients and steady state values for gating variables m , h , and n of HH equations.

The rate coefficients α and β are derived from the experimentally estimated time constants τ and steady-state values illustrated in Figure 1, for example,

$$\tau_m = 1/(\alpha_m + \beta_m), \quad m_0 = \alpha_m/(\alpha_m + \beta_m). \quad (7)$$

Numerical solution (on a mechanical hand calculator) of the membrane equations reproduced both the subthreshold and action potential responses to initial depolarizations and a decrease in latency seen with increasing amplitude above threshold.

Computations of the total conductance change during the membrane action potential; total ion fluxes, time course of refractory period, and damped oscillatory responses matched experimental observations. The equations were based on experiments performed at 6.3°C; a Q_{10} of 3 (increasing temperature by 10° caused the rates to increase by a factor of 3) allowed simulation of the temperature dependence of the action potential. A solitary propagating solution of Equations (1)–(6) was obtained by assuming a wave solution traveling with a constant velocity of θ and making a coordinate transformation $\xi = x - \theta t$ to reduce Equation (1) to an autonomous system of ordinary differential equations. A value of $\theta = 18.8 \text{ ms}^{-1}$ was found by trial and error to give an appropriately bounded solution in this traveling-coordinate system, which is close to the experimental estimate of 20 ms^{-1} . For this work Alan Hodgkin and Andrew Huxley shared the Nobel Prize in Physiology or Medicine in 1963.

Early digital computations showed the continuous HH membrane equations to have a quasi-threshold, with the size of the action potential increasing smoothly with stimulus intensity. This contradiction of the “all-or-none” nature of the nerve impulse required control of variables to a higher resolution than thermal noise would allow in practice. However, similar behavior was found both numerically and experimentally at high temperatures (Cole et al., 1970). The membrane equations respond to steady injected currents by a repetitive discharge with a rate from 50 to 125 s^{-1} , with a logarithmic relation between rate and injected current density, as found in sensory coding. The numerical and experimental responses to periodic stimulation include phase-locked, entrained, and even chaotic responses. The close agreement between numerical

Figure 2. Constant velocity travelling wave solution of HH equations. Transmembrane voltage (upper) and membrane permeability (lower).

and experimental results has allowed chaos in the periodically forced squid axon to be a test signal for the validation of methods of quantifying chaos.

The equations successfully reproduced experimental data on membrane potential, ionic currents, and ion fluxes and provided a quantitative theory for the excitation and propagation of the nerve impulse. The equations were an empirical description of the currents seen under voltage clamp that also gave a quantitatively accurate reconstruction of the action potential. The form of the equations suggested a simple model of gated pores, with each pore gated by a system of four independent gates, and each gate opening or closing independently, with voltage-dependent, first-order kinetics. This physical model, of gated ionic conductance channels, has been substantiated by the electrophysiological and molecular biological characterization of single ionic channels, their kinetics and gating (Hille, 2001). The Hodgkin–Huxley formalism has also been successfully applied to the analysis of excitable membranes of nerve, smooth, skeletal, and cardiac muscle.

The introduction of digital computing into bio-science laboratories allowed numerical solution of the full partial differential equation system (Cooley & Dodge, 1966). Both stable and unstable traveling-wave solutions are found (Rinzel & Keller, 1973), and the effects of changes in diameter and axonal branching have been described.

As the first quantitatively accurate description of excitation, the HH equations have been used as a prototype for studying the behavior of excitation cells in general, as well as in circumstances with parameter values that may have no biological relevance for the squid axon. The development of autorhythmicity, by changes in parameters (injected steady current, maximal conductances, extracellular ionic concentrations,

temperature), has been shown to be by simple Hopf bifurcation; the bifurcation curves in parameter space have been mapped (Holden & Winlow, 1984) and explained using singularity theory (Golubitsky & Schaeffer, 1985). The HH equations were in fact a case study for the first numerical package for using continuation algorithms to track Hopf bifurcation curves. Phase-resetting behavior and annihilation of repetitive activity by appropriately timed perturbations has been computed and found in experiments (Guttman et al., 1984).

The importance of the HH equations in physiology has led to interest from mathematicians, either by generalizing the equations to characterize the mathematical aspects of excitation (Carpenter, 1977) or to allow exotic behavior such as bursting or by simplifying the equations to allow analysis or to facilitate numerical computations.

HODOGRAPH TRANSFORM

Consider an N -component system with dependent variables

$$u(x, t) = [u_1(x, t), u_2(x, t), \dots, u_N(x, t)]$$

that satisfy the partial differential equations

$$\frac{\partial u_i}{\partial t} = \sum_{j=1}^N v_{ij}(u) \frac{\partial u_j}{\partial x}, \quad v_{ij}(u) \in \mathbb{R},$$

$$i = 1, \dots, N. \quad (1)$$

Under invertible smooth changes of variables of the form

$$u_i = u_i(w_1, w_2, \dots, w_N), \quad i = 1, 2, \dots, N, \quad (2)$$

the coefficients v_{ij} transform as a tensor,

$$v_{ij}(u_1, u_2, \dots, u_N) \rightarrow \tilde{v}_{rs}(w_1, w_2, \dots, w_N)$$

$$= \sum_{i,j=1}^N \frac{\partial w_r}{\partial u_i} v_{ij}(u(w)) \frac{\partial u_j}{\partial w_s}.$$

Now let us assume that the eigenvalues $\lambda_1, \lambda_2, \dots, \lambda_N$ of the matrix v_{ij} are real and distinct, so system (1) is hyperbolic. Then it is possible to reduce (1), using transformation (2) to a diagonal form

$$\frac{\partial w_i}{\partial t} = \lambda_i(w) \frac{\partial w_i}{\partial x}, \quad i = 1, 2, \dots, N, \quad (3)$$

where $w(x, t) = (w_1(x, t), w_2(x, t), \dots, w_N(x, t))$. The variables $w_1, w_2, \dots, w_N$ are called “Riemann invariants,” and the coefficients $\lambda_1(w), \lambda_2(w), \dots, \lambda_N(w)$ are the corresponding characteristic velocities.

For $N = 2$ it is always possible locally to reduce (1) to Riemann invariant form, while for $N \geq 3$ this is not true in general. When system (1) is reducible to the diagonal form (3), it is sometimes possible to integrate it through the so-called hodograph transform. For $N \leq 2$, this fact is well known (see Courant & Hilbert, 1962); while for $N \geq 3$, the result was proved by Tsarev (1985). Let us consider the two-component system

$$\frac{\partial w_1}{\partial t} = \lambda_1(w_1, w_2) \frac{\partial w_1}{\partial x},$$

$$\frac{\partial w_2}{\partial t} = \lambda_2(w_1, w_2) \frac{\partial w_2}{\partial x}. \quad (4)$$

To integrate (4), we map it into a linear set of equations, by interchanging the role of the dependent and independent variables, the so-called hodograph transform $(x, t) \rightarrow (w_1, w_2)$. In this transformation

$$\partial_2 x = -\frac{\partial_t w_1}{J}, \quad \partial_1 x = \frac{\partial_t w_2}{J},$$

$$\partial_2 t = \frac{\partial_x w_1}{J}, \quad \partial_1 t = -\frac{\partial_x w_2}{J},$$

where $x = x(w_1, w_2)$, $t = t(w_1, w_2)$, $\partial_i = \partial/\partial w_i$, $i = 1, 2$ and $J = \partial_x w_1 \partial_t w_2 - \partial_t w_1 \partial_x w_2$ is the Jacobian. Then system (4) is mapped into the linear equations

$$\partial_2 x + \lambda_1 \partial_2 t = 0, \quad \partial_1 x + \lambda_2 \partial_1 t = 0. \quad (5)$$

The hodograph transform guarantees a linear equation, but it may not be useful in practice. Let us write (5) in the equivalent form

$$\begin{aligned} \underbrace{\partial_2(x + \lambda_1 t)}_{x_1} &= t \partial_2 \lambda_1, \\ \underbrace{\partial_1(x + \lambda_2 t)}_{x_2} &= t \partial_1 \lambda_2. \end{aligned} \quad (6)$$

Then the functions $w_1(x, t)$ and $w_2(x, t)$, defined implicitly by

$$\begin{aligned} \chi_1(w_1, w_2) &= \lambda_1(w_1, w_2)t + x, \\ \chi_2(w_1, w_2) &= \lambda_2(w_1, w_2)t + x, \end{aligned} \quad (7)$$

solve (4) if

$$\frac{\partial_2 \chi_1}{\chi_1 - \chi_2} = \frac{\partial_2 \lambda_1}{\lambda_1 - \lambda_2}, \quad \frac{\partial_1 \chi_2}{\chi_2 - \chi_1} = \frac{\partial_1 \lambda_2}{\lambda_2 - \lambda_1}. \quad (8)$$

Indeed from (7)

$$t = \frac{\chi_1 - \chi_2}{\lambda_1 - \lambda_2},$$

and substituting the above into (6), we obtain the linear overdetermined system (8).

As an example, consider the Born–Infeld equation

$$(1 - \psi_t^2)\psi_{xx} + 2\psi_x\psi_t\psi_{xt} - (1 + \psi_x^2)\psi_{tt} = 0, \quad (9)$$

which was formulated by Max Born in the early 1930s as a nonlinear field model for elementary particles. It is a simple matter to check that either

$$\psi = \Psi(x - t) \quad \text{or} \quad \psi = \Psi(x + t)$$

are solutions of (9) for any function Ψ . In particular, the solution can be chosen in the form of a single hump to give the solitary wave appearance. The equation is hyperbolic for solution with $1 + \psi_x^2 - \psi_t^2 > 0$. We notice that the solitary waves have constant characteristic velocity ± 1 and avoid the usual breaking expected for nonlinear hyperbolic waves. Interacting waves for system (9) were obtained through the hodograph method by Barbishov & Chernikov (1966). First, if new variables

$$\xi = x - t, \quad \eta = x + t, \quad u_1 = \psi_\xi, \quad u_2 = \psi_\eta$$

are introduced, we obtain the equivalent system

$$\begin{aligned} \partial_\eta u_1 - \partial_\xi u_2 &= 0, \\ u_2^2 \partial_\xi u_1 - (1 + 2u_1 u_2) \partial_\eta u_1 + u_1^2 \partial_\eta u_2 &= 0. \end{aligned} \quad (10)$$

The Riemann invariants are

$$w_1 = \frac{\sqrt{1 + 4u_1 u_2} - 1}{2u_2}, \quad w_2 = \frac{\sqrt{1 + 4u_1 u_2} + 1}{2u_1},$$

so system (10) reduces to the form

$$\partial_\xi w_1 = w_2^2 \partial_\eta w_1, \quad \partial_\xi w_2 = \frac{1}{w_1^2} \partial_\eta w_2. \quad (11)$$

Performing the hodograph transform $(\eta, \xi) \rightarrow (w_1, w_2)$, system (11) is mapped to

$$w_1^2 \partial_1 \xi + \partial_1 \eta = 0, \quad \partial_2 \xi + w_2^2 \partial_2 \eta = 0,$$

where $\partial_1 \equiv \partial_{w_1}$ and $\partial_2 \equiv \partial_{w_2}$. Eliminating η leads to the simple form

$$\partial_1 \partial_2 \xi = 0.$$

The above equation is readily integrated as

$$\begin{aligned} x - t &= \xi = F(w_1) - \int w_2^2 G'(w_2) dw_2, \\ x + t &= \eta = G(w_2) - \int w_1^2 F'(w_1) dw_1, \end{aligned}$$

where F and G are arbitrary functions, and it follows that

$$\partial_1 \psi = w_1 F'(w_1), \quad \partial_2 \psi = w_2 G'(w_2).$$

It is convenient to introduce

$$\begin{aligned} F(w_1) &= \rho, \quad G(w_2) = \sigma, \\ w_1 &= \Phi_1'(\rho), \quad w_2 = \Phi_2'(\sigma), \end{aligned}$$

so that the corresponding expression for ψ reads

$$\begin{aligned} \psi &= \Phi_1(\rho) + \Phi_2(\sigma), \\ x - t &= \rho - \int_{-\infty}^{\sigma} \Phi_2'^2(\sigma) d\sigma, \\ x + t &= \sigma + \int_{\rho}^{+\infty} \Phi_1'^2(\rho) d\rho. \end{aligned}$$

If $\Phi_1(\rho)$ and $\Phi_2(\sigma)$ are localized, say, they are nonzero in $-1 < \rho < 0$ and $0 < \sigma < 1$, then

$$\psi = \Phi_1(x - t) + \Phi_2(x + t), \quad t < 0,$$

while for $t \rightarrow +\infty$, the solution approaches

$$\begin{aligned} \psi &= \Phi_1 \left(x - t + \int_{-\infty}^{\infty} \Phi_2'^2(\sigma) d\sigma \right) \\ &\quad + \Phi_2 \left(x + t - \int_{-\infty}^{+\infty} \Phi_1'^2(\rho) d\rho \right). \end{aligned}$$

Each wave receives a displacement in the direction opposite to its direction of propagation equal to

$$\int_{-\infty}^{+\infty} \Phi_i'^2(\tau) d\tau, \quad i = 1, 2.$$

The interaction is remarkably similar to the interaction of solitary waves even though the Born–Infeld equation belongs to a different class of systems. We remark that the above analysis is valid provided that the mapping from the (x, t) plane to the (ρ, σ) plane is nonsingular.

Application to Multiphase Averaging

The generalized hodograph method is used to integrate (Dubrovín & Novikov, 1989) the multiphase averaged equations or Whitham equations (Whitham, 1974; Flaschka et al., 1980). These equations are obtained by averaging conservation laws over the family of multiphase solutions of one-dimensional integrable nonlinear evolution equations like, for example, the Korteweg–de Vries equation. The Whitham equations describe the modulation of the wave parameters and wave numbers of the multiphase solutions over time and space scales of order εt and εx , where t and x are the independent variables of the original nonlinear evolution equations and $0 < \varepsilon \ll 1$. When the Whitham equations are hyperbolic, the technique of integration follows from a result of Tsarev (1985) that generalizes the hodograph transform to many dependent variables. The following condition is sufficient for integrability

$$\partial_i \left(\frac{\partial_k \lambda_j}{\lambda_k - \lambda_j} \right) = \partial_k \left(\frac{\partial_i \lambda_j}{\lambda_i - \lambda_j} \right), \\ i \neq j \neq k, \quad i, j, k = 1, \dots, N.$$

The integration of (3) is obtained as follows. If $\chi_1(w), \dots, \chi_N(w)$ solves the linear over-determined system

$$\partial_i \chi_j = \frac{\chi_i - \chi_j}{\lambda_i - \lambda_j} \partial_i \lambda_j, \quad i \neq j, \quad i, j = 1, \dots, N, \quad (12)$$

then the solution $w_1(x, t), \dots, w_N(x, t)$ of the generalized hodograph transform

$$x + \lambda_i(w)t = \chi_i(w), \quad i = 1, \dots, N,$$

satisfies (3). Conversely, every solution of (3) can be obtained in this way in the neighborhood of a point (x_0, t_0) where $\partial_x w_i, i = 1, 2, \dots, N$, is not vanishing. The solution of the linear over-determined system (12) corresponding to the Whitham equations can be obtained by algebro-geometric integration.

HOLE BURNING

Hole burning is a nonlinear technique for high-resolution spectroscopy, which was first demonstrated in magnetic resonance spectroscopy (Bloembergen et al., 1948). Hole burning employs the spectral purity of a laser to remove from an inhomogeneously broadened spectral line a narrow homogeneous line, causing a dip (or hole) in the spectrum. Thus, the technique is aimed at revealing the homogeneous line shape in the presence of strong inhomogeneous broadening.

The homogenous line shape is usually a Lorentzian whose full width $\Delta\omega_h$ is determined by the phase relaxation time T_2 of the system being considered

$$\Delta\omega_h = 1/T_2. \quad (1)$$

T_2 is itself composed of two different times T_1 and T_2^* . T_1 is the energy relaxation time, that is, the time by which a non-equilibrium population reaches equilibrium. T_2^* is the pure dephasing time, the time in which an ensemble of molecules randomizes its initial coherent motion. From the Bloch equation, it can be readily shown that

$$1/T_2 = 1/T_1 + 2/T_2^*. \quad (2)$$

Hence, the homogeneous line shape function contains all the information on energy relaxation and dephasing processes (Abragam, 1961).

The inhomogeneous width $\Delta\omega_i$ is often much larger than $\Delta\omega_h$, so that the homogeneous line shape is completely masked. Inhomogeneous line broadening occurs since the microenvironments of the molecules, atoms, etc. under consideration are different, so the respective resonance frequencies experience a dispersion. Accordingly, the associated line shape is, as a rule, a Gaussian. In magnetic resonance this dispersion has its origin in the field inhomogeneities, in optical spectroscopy it comes from structural imperfections of the matrix in which the probe molecule is embedded.

Hole burning is one possible method for revealing the homogenous line shape. It is a special variant of saturation spectroscopy for the case that $\Delta\omega_h \ll \Delta\omega_i$. There are two main branches of this technique, namely saturation via the power and saturation via the radiation dose of the applied field. A two-state system, for example, an electronic two-level system of a probe molecule in an imperfect lattice, can only be saturated

Figure 1. (a) Saturation of a three-level system. The storage level $|s\rangle$ is accessible from the excited state $|1\rangle$ by nonradiative processes. ω_L : laser frequency. (b) Schematic representation of the spectrum associated with saturation of the three-level system. $\Delta\omega_H$: holewidth. In the limit of vanishing saturation $\Delta\omega_H \rightarrow 2\Delta\omega_h$.

via the power of the radiation field: power is absorbed as long as there is a population difference between the lower and the upper state. As the power is increased, the population of the two states may equalize. Absorption and stimulated emission are balanced and the sample becomes transparent at the frequency of the radiation field. This phenomenon is called saturation. Note that power saturation of a two-level system is nonpersistent; that is, it decays with the energy relaxation time T_1 . If the radiation field is tuned through the saturated transition, a dip or "hole" appears in the spectrum. The width of the hole in a power-saturated transition, $\Delta\omega_p$, however, deviates from the width of the homogenous line-shape function because it depends via the so-called Rabi frequency ω_1 on the power of the saturating radiation:

$$\Delta\omega_p = \Delta\omega_h[1 + \omega_1^2 T_1 T_2]^{1/2}. \quad (3)$$

ω_1 is proportional to the amplitude of the radiation field. Note that although the width becomes power dependent, the shape of the power-saturated transition retains its Lorentzian shape.

A very different saturation process is associated with hole burning involving three levels (Gorokhovskii et al., 1974; Kharlamov et al., 1974). Although power-saturation of an electronic two-level system is possible, it is of much less importance compared with saturation processes involving three levels, say the groundstate of a molecule $|0\rangle$, its first excited singlet state $|1\rangle$, and a long-lived intermediate $|s\rangle$ that acts as a storage state (Figure 1a). This intermediate, for instance, could be a photochemical state, a structural (e.g., a conformational) state or a long-lived spin state. It is not directly accessible to the radiation field, but can only be populated from state $|1\rangle$ via some radiative or radiationless process. Upon irradiating the $|0\rangle \rightarrow |1\rangle$ transition with a laser, population from a small range around the laser frequency ω_L is transferred to $|s\rangle$. Accordingly, a hole appears around ω_L in the absorption spectrum (Figure 1b). This hole may be persistent if the

storage state $|s\rangle$ lives sufficiently long, as is the case for many photochemical states. In this case, the technique is called "photochemical hole burning." At sufficiently low temperatures, say, a few K, T_2^* becomes very large so that $\Delta\omega_h$ becomes lifetime-limited (Equations (1) and (2)). For a dye molecule with a typical lifetime of 10 ns dissolved in an organic glass, which gives rise to a typical inhomogeneous width of 300 wave numbers, this means that the burnt-in hole can be 4 to 5 orders of magnitude narrower than the inhomogeneous width. Because of this improvement in resolution, spectral hole burning is essentially a low-temperature technique (Friedrich & Haarer, 1984).

Persistent spectral hole burning may be characterized as a zero-power technique because holes can be burnt with vanishingly small power just by increasing the irradiation time. Yet, despite the fact that power saturation can be avoided, there is saturation broadening that, in contrast to the two-level case, depends on the irradiation dose: as population is transferred to the level $|s\rangle$, the number of absorbers in the center of the hole decreases steadily. Hence, the population transfer slows down in the center but still continues in the margins of the hole. This gives rise to an additional broadening in a similar way as has been discussed above for power broadening. Accordingly, $\Delta\omega_h$ is obtained from an extrapolation of the hole width to zero radiation dose.

Since the power of the radiation field can be made vanishingly small, the optics itself is perfectly linear. The nonlinear behavior of optical hole burning comes in via the persistent changes of the complex index of refraction through the irradiated energy. The advantage of the technique lies in the persistency of these changes. This makes it easy to exploit the high resolution, for instance, in measuring the influence of small external perturbations in the presence of strong inhomogeneous broadening, such as the influence of small electric, magnetic, or pressure fields. Persistent hole burning has been one of the major techniques to investigate the dynamics of low-temperature glasses via so-called spectral diffusion experiments

(Friedrich & Haarer, 1986), and it has gained much attraction in high-resolution spectroscopy of biological molecules (Friedrich, 1995). There are also quite a few technical applications, mostly in optical data storage (Moerner, 1988).

HOLONS

In the literature on nonlinear science, the term *holon* has arisen in two quite different senses: as a type of elementary quantum excitation and in the context of emergent biological and social phenomena.

Holons in Physics

In the physics community, holons are particles with zero spin and charge ± 1 (in units of electron charge e) obtained in the fractionalization of an electron or a hole. They are related to the phenomena of spin-charge separation and fractionalization and are the supersymmetric partner of spinons—particles with zero charge and spin $\frac{1}{2}$. Holons and spinons are neither bosons (statistics 0) nor fermions (statistics -1) (statistics α represents the phase that the two-particle wavefunction accumulates when one particle is taken and moved around another), but obey fractional statistics $\frac{1}{2}$ and are, therefore, called semions.

Recently, it has become possible to experimentally realize one-dimensional samples by growing crystals, such as KCuF_3 , SrCuO_2 , or Sr_2CuO_3 , with strong

anisotropy due to antiferromagnetic spin-spin interaction. Photoemission spectroscopy experiments on these crystals show two distinct bands in the energy dispersion, one belonging to the spinon, and the other to the holon. In theory and in experiments, holons have been observed only in one spatial dimension (Kim et al., 1996, 1997; Fujisawa et al., 1998, 1999), with credible efforts to discover them in higher dimensions having remained so far unsuccessful.

The simplest model where holons show up is the supersymmetric t - J model with $1/r^2$ interaction (Kuramoto–Yokohama (KY)-model) (Kuramoto & Yokohama, 1991). This is a system of electrons on a lattice with periodic boundary conditions, where it is forbidden that two electrons be on the same lattice site. Electrons can hop from site to site, there is a Coulomb interaction term, and there are also antiferromagnetic spin-spin interactions. The Hamiltonian is supersymmetric, in the sense that it costs zero energy for a charge to be introduced in the system. The elementary excitations of the system are spinons and holons. The holons have a dispersion relation:

$$E = -\frac{J}{2} \left[\left(\frac{\pi}{2} \right)^2 - q^2 \right], \quad (1)$$

where E is the holon energy, q is the holon momentum, and J is an energy scale in the system. The configuration space of positive energy holons is halved with respect to that of an integral particle. Although the equations governing the dynamics of spinons and holons are different, they yield the same form for the interaction between a holon and a spinon and between two spinons. The interaction between the holon and the spinon in one spatial dimension is inversely proportional to the distance between these particles. When the holon and the spinon are at the same point in space, the interaction between them is divergent and together they form the electron. However, the interaction does not diverge fast enough to prevent an instability of the electron toward decay into the two particles, and indeed there is a small but finite matrix element for electron to holon and spinon decay.

An experimentally accessible quantity is the spectral function for a holon-spinon pair:

$$A_{\text{holon-spinon}}(\omega, q) = \frac{1}{\pi^2 J q} \sqrt{\frac{J[q + \frac{\pi}{2}]^2 - \omega}{\omega - J[q - \frac{\pi}{2}]^2}} \times \Theta \left[\omega - J[q - \frac{\pi}{2}]^2 \right] \Theta \left[J \frac{\pi^2}{4} + q(\pi - q) - \omega \right], \quad (2)$$

where ω and q are the energy and momentum at which the measurements are being conducted and J is the relevant energy scale in the system. The

physical consequence of these measurements is the proof of instability of the electron, which is no longer a legitimate excitation of the system but breaks up into a holon and a spinon (Bernevig et al., 2001, 2002).

Holons in Biological and Social Systems

Biological and social systems are typically organized as hierarchies, in which nonlinear dynamics at each level of the hierarchy leads to the emergence of new dynamic entities that provide a basis for the nonlinear dynamics of the next higher level (Scott, 1995).

A well-known example of such a hierarchy is the structure of a military unit. Thus, an infantry division comprises four regiments, each of which comprises four battalions, which consist of four companies, and so on, up to 15,000 individual riflemen. Similar hierarchical structure is displayed by living organisms—for example, a human being is composed of a collection of organs, and the organs are composed of cells, which are made up of biochemicals (proteins, DNA, etc.), down to our constituent atoms.

In the 1960s, Arthur Koestler proposed the term *holon* to imply a general feature of a biological or social system that has a unique identity, yet is made up of lower-level features that comprise parts of the whole (Koestler, 1968). In this sense, holons are components of complex dynamic systems that are efficient and adaptable to disturbances, both internal and external. For example, you are a holon, as is your liver and each of your skin cells.

Interestingly, the human neocortex seems also to be hierarchically organized into closely interconnected assemblies of neurons that embody the holonic components of complex thought (Scott, 1995, 2002).

HOPF BIFURCATION

The term *Hopf bifurcation* (also called Poincaré–Andronov–Hopf bifurcation) refers to the local birth or death of a periodic solution (self-excited oscillation) from an equilibrium as a parameter crosses a critical value. It is the simplest bifurcation not just involving equilibria and, therefore, belongs to what is sometimes called dynamic (as opposed to static) bifurcation theory. In a differential equation, a Hopf bifurcation typically occurs when a complex conjugate pair of eigenvalues of the linearized flow at a fixed point becomes purely imaginary. This implies that a Hopf bifurcation can only occur in systems of dimension two or higher.

That a periodic solution should be generated in this event is intuitively clear from Figure 1. When the real parts of the eigenvalues are negative the fixed point is a stable focus (Figure 1(a)); when they cross zero and become positive the fixed point becomes an unstable focus, with orbits spiralling out. But this change of stability is a local change, and the phase portrait sufficiently far from the fixed point will be qualitatively unaffected. If the nonlinearity makes the far flow contracting, then orbits will still be coming in and we expect a periodic orbit to appear

Figure 1. Phase portraits of (2) for (a) $\mu = -0.2$, (b) $\mu = 0.3$. There is a supercritical Hopf bifurcation at $\mu = 0$.

where the near and far flow find a balance (as in Figure 1(b)).

The Hopf bifurcation theorem makes the above precise. Consider the planar system

$$\begin{aligned}\dot{x} &= f_\mu(x, y), \\ \dot{y} &= g_\mu(x, y),\end{aligned}\quad (1)$$

where μ is a parameter. Suppose it has a fixed point that without loss of generality, we may assume to be located at the origin of the (x, y) plane. Let the eigenvalues of the linearized system about this fixed point be given by $\lambda(\mu)$, $\bar{\lambda}(\mu) = \alpha(\mu) \pm i\beta(\mu)$. Suppose further that for a certain value of μ (which we may assume to be zero), the following conditions are satisfied:

- (i) $\alpha(0) = 0$, $\beta(0) = \omega \neq 0$
(nonhyperbolicity condition: conjugate pair of imaginary eigenvalues);
- (ii) $\left. \frac{d\alpha(\mu)}{d\mu} \right|_{\mu=0} = d \neq 0$
(transversality condition: eigenvalues cross imaginary axis with nonzero speed);
- (iii) $a \neq 0$, where

$$\begin{aligned}a &= \frac{1}{16} (f_{xxx} + f_{xyy} + g_{xxy} + g_{yyy}) \\ &\quad + \frac{1}{16\omega} (f_{xy}(f_{xx} + f_{yy}) - g_{xy}(g_{xx} + g_{yy}) \\ &\quad - f_{xx}g_{xx} + f_{yy}g_{yy}),\end{aligned}$$

with $f_{xy} = (\partial^2 f_\mu / \partial x \partial y)|_{\mu=0}(0, 0)$, etc. (genericity condition).

Then a unique curve of periodic solutions bifurcates from the origin into the region $\mu > 0$ if $ad < 0$ or $\mu < 0$ if $ad > 0$. The origin is a stable fixed point for $\mu > 0$ (resp. $\mu < 0$) and an unstable fixed point for $\mu < 0$ (resp. $\mu > 0$) if $d < 0$ (resp. $d > 0$), while the periodic solutions are stable (resp. unstable) if the origin is unstable (resp. stable) on the side of $\mu = 0$, where the periodic solutions exist. The amplitude of the periodic orbits grows like $\sqrt{|\mu|}$ while their periods tend to $2\pi/|\omega|$ as $|\mu|$ tends to zero. The bifurcation is called “supercritical” if the bifurcating periodic solutions are stable, and “subcritical” if they are unstable.

This two-dimensional version of the Hopf bifurcation theorem was known to Alexandr A. Andronov and his co-workers from around 1930 (Andronov et al., 1966) and had been suggested by Henri Poincaré (1892). Eberhard Hopf (1942) proved the result for arbitrary (finite) dimensions. Through center-manifold reduction, the higher-dimensional version essentially reduces to the planar one provided that apart from the two purely imaginary eigenvalues no other eigenvalues have zero real part. In his proof (which predates the center-manifold theorem), Hopf assumes the functions f_μ and g_μ to be analytic, but C^5 differentiability is sufficient (a proof can be found in Marsden & McCracken (1976)). Extensions exist to infinite-dimensional problems such as differential delay equations and certain classes of partial differential equations (including the Navier–Stokes equations) (e.g., Marsden & McCracken, 1976, Sections 8 and 9).

Example. Consider the oscillator $\ddot{x} - (\mu - x^2)\dot{x} + x = 0$ (an example of a so-called Liénard system), which, with $u = x$, $v = \dot{x}$, we can write as the first-order system

$$\begin{aligned}\dot{u} &= v, \\ \dot{v} &= -u + (\mu - u^2)v.\end{aligned}\quad (2)$$

The origin is a fixed point for each μ , with eigenvalues $\lambda(\mu)$, $\bar{\lambda}(\mu) = \frac{1}{2}(\mu \pm i\sqrt{4 - \mu^2})$. The system has a Hopf bifurcation at $\mu = 0$. We have $d = \frac{1}{2}$ and $a = -\frac{1}{8}$, so the bifurcation is supercritical and there is a stable isolated periodic orbit (limit cycle) if $\mu > 0$ for each sufficiently small μ (see Figure 1).

Hopf Bifurcation for Maps

There is a discrete-time counterpart of the Hopf bifurcation that occurs when a pair of complex conjugate eigenvalues of a map crosses the unit circle. It is slightly more complicated than the version for flows. The corresponding theorem was first proved independently by Naimark (1959) and Sacker (1965), and the bifurcation is, therefore, sometimes called the Naimark–Sacker bifurcation. A proof can again be found in Marsden & McCracken (1976).

Consider the planar map $f_\mu: \mathbb{R}^2 \rightarrow \mathbb{R}^2$, with parameter μ , and suppose it has a fixed point that without loss of generality, we may assume to be located at $(x, y) = (0, 0)$. Suppose further that at this fixed point, Df_μ has a complex conjugate pair of eigenvalues $\lambda(\mu)$, $\bar{\lambda}(\mu) = |\lambda(\mu)|e^{\pm i\omega(\mu)}$ and that for a certain value of μ (which we may assume to be 0), the following conditions are satisfied:

- (i) $|\lambda(0)| = 1$ (nonhyperbolicity condition: eigenvalues on the unit circle);
- (ii) $\lambda^k(0) \neq 1$ for $k = 1, 2, 3, 4$ (nonstrong-resonance condition);
- (iii) $\frac{d|\lambda(\mu)|}{d\mu}\bigg|_{\mu=0} = d \neq 0$ (transversality condition);
- (iv) $a \neq 0$, where

$$a = -\operatorname{Re} \left[\frac{(1-2e^{ic})e^{-2ic}}{1-e^{ic}} c_{11} c_{20} \right] - \frac{1}{2} |c_{11}|^2 - |c_{02}|^2 + \operatorname{Re}(e^{-ic} c_{21}), \quad c = \omega(0),$$

with

$$c_{20} = \frac{1}{8}[(f_{xx} - f_{yy} + 2g_{xy}) + i(g_{xx} - g_{yy} - 2f_{xy})],$$

$$c_{11} = \frac{1}{4}[(f_{xx} + f_{yy}) + i(g_{xx} + g_{yy})],$$

$$c_{02} = \frac{1}{8}[(f_{xx} - f_{yy} - 2g_{xy}) + i(g_{xx} - g_{yy} + 2f_{xy})],$$

$$c_{21} = \frac{1}{16}[(f_{x_{xx}} + f_{x_{yy}} + g_{x_{xy}} + g_{y_{yy}})$$

$$+ i(g_{x_{xx}} + g_{x_{yy}} - f_{x_{xy}} - f_{y_{yy}})]$$

(genericity condition).

Then an invariant simple closed curve bifurcates into either $\mu > 0$ or $\mu < 0$, depending on the signs of d and a . This invariant circle is attracting if it bifurcates into the region of μ where the origin is unstable (a supercritical bifurcation) and repelling if it bifurcates into the region where the origin is stable (a subcritical bifurcation).

Note that this result says nothing about the dynamics on the invariant circle. In fact, the dynamics on the circle has the full complexity of so-called “circle maps” (including the possibility of having attracting periodic orbits on the invariant circle) and depends sensitively on any perturbation (see the example

below). Consequently, unlike the Hopf bifurcation for flows, the Hopf bifurcation for maps is not structurally stable.

Example. Consider the following family of maps:

$$\begin{aligned} f_\mu \begin{pmatrix} x \\ y \end{pmatrix} &= (1 + d\mu + a(x^2 + y^2)) \\ &\times \begin{pmatrix} \cos(c + b(x^2 + y^2)) & -\sin(c + b(x^2 + y^2)) \\ \sin(c + b(x^2 + y^2)) & \cos(c + b(x^2 + y^2)) \end{pmatrix} \\ &\times \begin{pmatrix} x \\ y \end{pmatrix}. \end{aligned} \quad (3)$$

The origin $(x, y) = (0, 0)$ is a fixed point for each μ . The Jacobian matrix of f_μ at this fixed point is

$$Df_\mu(0, 0) = (1 + d\mu) \begin{pmatrix} \cos c & -\sin c \\ \sin c & \cos c \end{pmatrix} \quad (4)$$

and the eigenvalues are $\lambda(\mu)$, $\bar{\lambda}(\mu) = (1 + d\mu)e^{\pm ic}$. The map takes a simpler, semi-decoupled form in polar coordinates $r = \sqrt{x^2 + y^2}$, $\theta = \arctan(y/x)$:

$$\begin{pmatrix} r \\ \theta \end{pmatrix} \mapsto \begin{pmatrix} r(1 + d\mu + ar^2) \\ \theta + c + br^2 \end{pmatrix}. \quad (5)$$

This five-parameter map is in fact the *normal form* for the Hopf bifurcation up to cubic terms (i.e., by a smooth change of coordinates, we can bring any f_μ into this form (plus higher-order terms)). The parameters a , c , and d in (3) and (5) are precisely those defined in the conditions above. We choose $a = -0.02$, $b = c = 0.1$, $d = 0.2$. The map then undergoes a supercritical Hopf bifurcation at $\mu = 0$, as can be confirmed by a simple graphical analysis of the decoupled r map (for $a > 0$, it would be subcritical). For sufficiently small $\mu > 0$, we have an attracting invariant circle given by $r = \sqrt{-d\mu/a}$ (see Figure 2). On the circle the map is given by $\theta \mapsto \theta + c - bd\mu/a$. This is simply a rotation through a fixed angle $\phi = c - bd\mu/a$, giving periodic orbits if $2\pi/\phi \in \mathbb{Q}$, or dense (irrational) orbits if $2\pi/\phi \in \mathbb{R} \setminus \mathbb{Q}$.

If the Hopf bifurcation occurs in a map associated with the return map (Poincaré map) near a periodic orbit of an autonomous flow, then the bifurcation is often called a secondary Hopf bifurcation. In this case, the invariant curve corresponds to an invariant torus because the flow and attracting periodic orbits on the circle correspond to mode-locked periodic motion on the torus, while dense orbits correspond to quasi-periodic motion.

Degenerate Hopf Bifurcations

If one or more of the listed conditions for a Hopf bifurcation are not satisfied (for instance, because of symmetry), one may still have the emergence of a

Figure 2. Phase portraits of (3) for (a) $\mu = -0.2$, (b) $\mu = 0.2$. There is a supercritical Hopf bifurcation at $\mu = 0$. ($a = -0.02$, $b = c = 0.1$, $d = 0.2$.)

periodic orbit, but some of the conclusions of the theorem may cease to hold true. The bifurcation is then called a “degenerate Hopf bifurcation.” For instance, if the transversality condition is not fulfilled, the fixed point may not change stability, or multiple periodic solutions may bifurcate. An important case is provided by a Hamiltonian system for which complex eigenvalues come in symmetric quadruples, and therefore, the transversality condition cannot be satisfied. This is why the analogous bifurcation in Hamiltonian systems (the so-called “Hamiltonian–Hopf bifurcation” (van der Meer, 1985)) is much more complicated requiring, for one thing, a four-dimensional phase space.

Applications

The balance between local excitation and global damping mentioned above occurs commonly in physical systems. Thus, the Hopf bifurcation underlies many spontaneous oscillations, including airfoil flutter and other wind-induced oscillations (for example, the Tacoma–Narrows bridge collapse) in structural engineering systems, vortex shedding in fluid flow around

a solid body at sufficiently high stream velocity, LCR oscillations in electrical circuits, relaxation oscillations (the van der Pol oscillator), the periodic firing of neurons in nervous systems (the FitzHugh–Nagumo equation), oscillations in autocatalytic chemical reactions (the Belousov–Zhabotinsky reaction) as described by the Brusselator and similar models, oscillations in fish populations (as described by Volterra’s predator–prey model), and periodic fluctuations in the number of individuals suffering from an infectious disease (as described by epidemic models), among others.

HORSESHOES AND HYPERBOLICITY IN DYNAMICAL SYSTEMS

In dynamical systems, *hyperbolicity* refers to the phenomenon in which nearby orbits diverge exponentially fast. It implies instability and sensitive dependence on initial conditions; when occurring on a wide enough scale, it implies *chaos*. This entry surveys and puts into perspective the core ideas in hyperbolic theory, one of the most developed branches in the mathematical theory of dynamical systems today.

For definiteness, we discuss only discrete-time systems, that is, systems generated by the iteration of a map f of a space (usually Euclidean space or a manifold) to itself, leaving analogous results in the continuous-time case to the reader.

Hyperbolic Fixed Points

A linear map $T : \mathbb{R}^n \rightarrow \mathbb{R}^n$ is called hyperbolic if none of its eigenvalues lies on the unit circle. A nonlinear map f is said to have a hyperbolic fixed point p if $f(p) = p$ and $Df(p)$ is a hyperbolic linear map. Thus, there are three kinds of hyperbolic fixed points: attracting (when the moduli of all the eigenvalues of $Df(p)$ are < 1), repelling (when they are all > 1), and saddle type (when some are > 1 and some are < 1). In the saddle case, p has a stable manifold $W^s(p)$ and an unstable manifold $W^u(p)$ consisting of points the orbits of which tend to p in forward and backward time, respectively.

Smale’s Horseshoe

Stephen Smale’s horseshoe (Smale, 1967) can be seen as a globalization of the idea of a saddle-type fixed point to an invariant set with complicated dynamics. Geometrically, the presence of a horseshoe implies stretching and folding. In terms of orbit types, it implies the existence of random motion as unpredictable as the repeated flipping of a coin (see below).

A version of the horseshoe map is shown in Figure 1: f stretches the square B in the horizontal direction, compresses it in the vertical direction, bends the resulting rectangle into the shape of a horseshoe, and puts it back on top of B as shown. The two shaded vertical strips are mapped onto the two shaded horizontal strips, the union of which is equal to $B \cap f(B)$. Reasoning inductively, we see that after n iterates, $\cap_{i=0}^n f^i(B)$ is the union of 2^n disjoint horizontal strips. Iterating backwards as well as forwards, we see that Λ , the set of points that remain in B in all forward and backward times, is the product of two Cantor sets.

If we label the left vertical strip in B “L” and the right one “R” (or “head” and “tail”), then every point x in Λ can be coded into a bi-infinite sequence of L and R where the i th coordinate is L if and only if $f^i x$ is in the left strip. It is easy to see that this defines a one-to-one correspondence between the points in Λ and the set of all possible bi-infinite strings in L and R. An immediate consequence of this coding is that Λ contains many periodic points, one corresponding to each finite block of L and R.

By *horseshoes*, one generally refers to a much larger class of objects than that depicted in Figure 1. The map f is assumed to be invertible, but it does not have to be linear anywhere. There is a box B (or a region B that can be deformed into a box) that is stretched and compressed by f and mapped to a set, which crosses over B finitely many times. Moreover, for points that remain in B , f has well-defined expanding and contracting directions, that is, it is hyperbolic. For an n -dimensional analog of the linear

Figure 1. The horseshoe map: f sends the square B to the horseshoe on the right.

model in Figure 1, imagine $B = D_k \times D_{n-k}$, where the “horizontal” direction represents a k -dimensional disk and the “vertical” direction an $(n - k)$ -dimensional disk (see also the Smale solenoid picture in the color plate section).

Smale’s idea for the horseshoe was influenced by the work of Norman Levinson, who in the late 1940s studied a simplified version of the periodically forced van der Pol equation and proved that the resulting oscillator contains infinitely many periodic orbits with distinct periods. This map was shown to have a horseshoe by M. Levi many years later.

Dynamical complexity near homoclinic orbits was noted by Henri Poincaré. (A homoclinic point is a point in $W^s(p) \cap W^u(p)$ where p is a fixed point of saddle type; See **Phase space**.) An important result due to Smale says that transverse homoclinic orbits are always accompanied by horseshoes. Thus, locating transverse, homoclinic points is a means of detecting chaos.

Finally, while the presence of horseshoes implies the existence of chaotic behavior, it should be pointed out that from the probabilistic or observational point of view, this may be transient chaos. The reasons are as follows. Horseshoes have Lebesgue measure zero. It is possible to have a horseshoe Λ and at the same time for the orbit of almost every point to go to a stable equilibrium. In such a scenario, a typical orbit may come near Λ , spend some time near Λ mimicking its orbits, before it heads for its eventual destination. An experimenter tracking this orbit will observe chaotic behavior but only for a finite time period.

Uniform and Non-uniform Hyperbolicity

More general than the idea of a horseshoe is that of a uniformly hyperbolic invariant set. Let f be a smooth invertible map. A compact f -invariant set Λ is called uniformly hyperbolic if everywhere on Λ , the tangent space splits into Df -invariant subspaces $E^u \oplus E^s$, with $\|Df(v)\| > \|v\|$ for $v \in E^u$, $\|Df(v)\| < \|v\|$ for $v \in E^s$, $v \neq 0$. From the 1960s to 1970s, a detailed theory was developed for a class of dynamical systems that are uniformly hyperbolic either on their entire phase spaces or on certain important invariant sets. This theory is called Axiom A theory or uniform hyperbolic theory.

A weaker form of hyperbolicity was introduced in the 1970s. The setting here consists of a pair (f, μ) where f is a map and μ is an f -invariant Borel probability measure. Oseledec’s multiplicative

ergodic theorem says that at μ -almost every x , the limit $\lim_{n \rightarrow \infty} \frac{1}{n} \log \|Df^n(x)v\| = \lambda(x, v)$ exists for every tangent vector v . These asymptotic growth rates are called *Lyapunov exponents*. The pair (f, μ) is said to be non-uniformly hyperbolic if there is a positive measure set of x such that $\lambda(x, v) > 0$ for some v and < 0 for other v ; that is, there is some expansion and some contraction. Pesin's paper (Pesin, 1977) helped launch a systematic study of these systems. The hyperbolicity here is non-uniform in the sense that there may be points that take arbitrarily long for the expanding and contracting behaviors to manifest themselves. Indeed, on a set of μ -measure zero, the limit above may not exist.

We put into perspective the ideas introduced: Horseshoes are examples of uniformly hyperbolic sets. They occur widely, and their occurrence does not preclude other types of dynamical behaviors. Axiom A is a more stringent condition; it requires that all important parts of the phase space be uniformly hyperbolic. This idealized picture excludes many real-life examples; at the same time it has permitted the development of a rich and extensive theory, one that is useful beyond Axiom A. As for the relation between uniform and non-uniform settings, the latter is clearly more flexible and therefore larger in scope. But the contexts are not identical: the properties of (f, μ) depend on μ , and most maps have many invariant measures. Not all invariant measures are equally important, however (See **Sinai–Ruelle–Bowen measures**). To complete this circle of ideas, we mention the following result of Katok: if a non-uniformly hyperbolic system has positive entropy and no zero Lyapunov exponents, then nearly all of its entropy is carried by horseshoes.

For more on uniform hyperbolic theory, See **Anosov and Axiom-A systems**.

Highlights from General Non-uniform Theory

The results below are very general. They hold for *all* invertible maps f (for which both f and f^{-1} are twice continuously differentiable) acting on compact domains in finite dimensions. For more detailed expositions, see Eckmann and Ruelle (1985) and Young (1993).

- (1) *Local nonlinear theory* (Pesin, 1977): It is shown that corresponding to negative and positive Lyapunov exponents are measurable families of local stable and unstable manifolds.
- (2) *Structure of conservative systems*, that is, when μ has a density (Pesin, 1977): Assume there are no zero Lyapunov exponents. Then the phase space is made up of at most countably many ergodic components, each one of which is, up to a permutation of sets, mixing.

- (3) *Relation among entropy, Lyapunov exponents, and dimension*: For conservative systems, there is the following entropy formula (Pesin, 1997):

$$h_\mu(f) = \int \sum_{\lambda_i > 0} \lambda_i m_i \, d\mu.$$

Here $h_\mu(f)$ is Kolmogorov–Sinai entropy, and the λ_i are distinct Lyapunov exponents with multiplicity m_i . In general, i.e. for arbitrary invariant measures, “=” in the formula above is replaced by “ $\leq$ ” (Ruelle, 1978), and dimension enters to give the following equalities (Ledrappier–Young, 1985):

$$h_\mu(f) = \int \sum_{\lambda_i > 0} \lambda_i \delta_i \, d\mu = - \int \sum_{\lambda_i < 0} \lambda_i \delta_i \, d\mu.$$

Here δ_i is a notion of *partial dimension*; it gives the dimension of μ in the direction of the subspace of vectors whose growth rates are equal to λ_i ; in particular $0 \leq \delta_i \leq m_i$. Together the results in (3) express the following two basic principles: randomness is created entirely from expansion; and dissipation can be measured in “wasted” expansion, that is, by the gap in Ruelle’s inequality or, equivalently, by the dimensions of the invariant measure.

- (4) *Sinai–Ruelle–Bowen (SRB) measures*: A special invariant measure (to play the role of volume) has been identified for dissipative systems with strange attractors (See **Sinai–Ruelle–Bowen measures**).

Examples

A large number of dynamical systems are believed to fit into the framework of non-uniform hyperbolic theory, but relatively few (that are not uniformly hyperbolic) have been rigorously studied. This is due in part to technical difficulties in proving the positivity of Lyapunov exponents in the absence of invariant cones (See **Lyapunov exponents**). Among the systems successfully analyzed, the most prominent are (1) Billiards flows, both scattering billiards (including the periodic Lorentz gas) and some focusing billiards (including the stadium), and geodesic flows on manifolds of nonpositive curvature. These systems are conservative and have natural invariant measures. (2) One-dimensional maps (such as the logistic family) and a class of attractors with one direction of instability (including the Hénon maps). For these maps, μ either has a density or is an SRB measure.

HURRICANES AND TORNADOES

As examples of nonlinear emergent structures, hurricanes and tornadoes are both violent and destructive atmospheric storms, albeit of different scales: a hurricane is much larger than a tornado and lives longer. The word *hurricane* derives from the Spanish word *huracan* which, in turn, stems from the Caribbean name for the god of evil; *tornado* is a variant of the Spanish *tronada* for thunderstorm. Both are associated with very strong winds circling around a center, called the eye, which is the calmest region of the storm with the lowest pressure.

Due to the Coriolis force (which stems from the Earth's rotation), hurricane winds spiral around the eye in a counter-clockwise direction in the Northern Hemisphere, whereas in the Southern Hemisphere the opposite is true. The term *hurricane* is often restricted to storms occurring in the North Atlantic Ocean; the same phenomenon over the West Pacific Ocean is called a typhoon, and in the South Pacific, a cyclone. For simplicity, in what follows, the term *hurricane* is used for the entire phenomenon.

A hurricane forms as a tropical cyclone in areas over warm ocean waters (at temperatures over 26.5°C) under a number of other preconditions such as a moist atmosphere with a sufficiently strong vertical temperature gradient, and latitudes exceeding approximately 8° from the equator (the latter condition provides sufficient Coriolis force to create a wind rotation). Its energy source is associated with latent heat release. The low-pressure center takes in thermal energy and moisture from the ocean surface, the warm air ascends because of convection, and the higher pressure in the cold upper levels of the atmosphere pushes it outward. When the warm air ascends it cools and the temperature of the air may fall below its dew point, releasing water vapor that is able to condense into water droplets. The

Figure 2. Photo of a tornado in Seymour, Texas (1979). Courtesy of National Oceanic and Atmospheric Administration.

condensation releases heat that in turn warms the air, increasing its ascent; at this stage the storm works as a self-sustaining heat engine. When the wind speed exceeds 74 mph (119 km h^{-1}), the tropical cyclone is classified as a hurricane. In some hurricanes wind speeds reach over 280 km h^{-1} . A mature hurricane is nearly circularly symmetrical (see Figure 1) and is moved by the airstreams in which it is embedded.

A tornado is a dark, funnel-shaped cloud containing violently rotating air that extends downward to the Earth (Figure 2). It is often accompanied by lightning and a roaring sound. Although it is not yet completely known how tornadoes form, the mechanism of tornado formation is presently attributed to mechanical and thermodynamical processes (the role of atmospheric electricity is disputable). Tornadoes are formed within massive and powerful storms called supercells. The supercells develop inside cumulonimbus clouds, which owe their name to the Latin *cumulus*, meaning mound or heap, and *nimbus*, which refers to rain. Cumulonimbus clouds may reach up to 18 km into the stratosphere, where the distinctive anvil-shaped top of a cloud

consisting of ice crystals is formed. Cumulonimbus clouds often form along a squall line (a wall of clouds and harsh weather often associated with a cold front) where, as a result of convective instability, a supercell is generated.

Once a supercell storm is formed, wind shear creates a mesocyclone, a region of rotating updrafts within a mature thunderstorm. Eventually, the mesocyclone reaches below the cumulonimbus cloud, whereupon it is considered a tornado cyclone. As air is pulled into the tornado cyclone, the water vapor condenses into a visible funnel cloud. When the latter touches the surface of the Earth, it is finally considered a full-fledged tornado. As time goes on, the tornado takes on a brownish color because of the dirt and debris it has drawn in. This whole process is termed the organizational stage, which leads to the mature stage when the tornado is at its largest and strongest. Eventually, when its source of warm, humid air is gone, the tornado begins to degenerate. This occurs when the atmosphere is finally stabilized due to convective processes. The tornado enters a shrinking stage and begins gradually weakening as it loses fuel. The funnel decreases to a thin column and becomes fragmented and disorganized in the decaying stage, although it may still remain destructive.

Hurricanes and tornadoes are destructive atmospheric phenomena, and not only because of strong winds. Since both hurricanes and tornadoes are storms, they are typically associated with excessive rainfall that can cause flooding. Another side effect of a hurricane is the so-called storm surge, which occurs when the ocean rises above its normal tide level. In fact, a hurricane can cause even more damage through storm surge than through strong winds. Still another potential side effect is the formation of tornadoes by thunderstorms embedded in the rainbands of a hurricane.

Both hurricanes and tornadoes are categorized by their wind speeds, from weak to devastating or violent, under the Saffir-Simpson scale for hurricanes and the Fujita-Pearson scale for tornadoes. While a hurricane can be hundreds of kilometers in diameter, the diameter of an average tornado is approximately 400 m. Tornadoes generally last from several minutes to several hours, and they travel up to several hundred kilometers before dying, whereas hurricanes last for several days and travel much greater distances. In the United States, about six hurricanes and 600 tornadoes are reported in an average year.

Some typical parameters of hurricanes and tornadoes are given in Table 1.

Since 1950, hurricanes have been given human names, such as Betty or George. Each year a new

	Hurricanes	Tornadoes
Wind speed (kph)	119–300	60–over 500
Diameter	200–1300 km	few m–1.5 km
Lifetime	1–30 days	1–180 min

Table 1. Some parameters of hurricanes and tornadoes (by order of magnitude).

list of names is made, with male and female names alternating alphabetically, and the lists are reused every six years. Examples of exceptionally deadly hurricanes are the one that occurred in the Bay of Bengal in 1737, which claimed about 300,000 lives, many lost to the huge sea waves; and an 1881 typhoon in China with a similar death toll. More recent examples include the typhoon Vera (1959) that struck central Japan, causing over 5000 deaths and destroying about 40,000 homes; the hurricane Flora (1963), which presumably killed more than 6000 people in the Caribbean area, and Camille (1969), with 256 casualties and over 5 billion dollars of damage in the southern United States. The most destructive United States hurricane of record was hurricane Andrew. It blasted its way across south Florida on August 24, 1992; Louisiana and the Bahamas were also impacted. The hurricane caused 26.5 billion dollars in damage in the United States, mainly due to the winds.

Regarding tornadoes in the United States, extremely destructive was the Tri-State Tornado of 1925, which killed 689 people and injured nearly 2000. In the United States, tornadoes are most prevalent in "Tornado Alley," a group of central plains states. Since the terrain there is relatively flat, warm air coming up from the Gulf of Mexico and cold air coming down from Canada often clash, to form some of the most fertile tornado-producing storms in the world. One such tornado hit central Oklahoma in May 1999. Actually, it was a tornado outbreak—a collection of tornadoes all striking at the same time in the same general area. More than 70 tornadoes were observed in the region of Kansas, Oklahoma, and Texas. They caused 40 deaths and injured 675 people, with total damages estimated at 1.2 billion dollars.

From the physical viewpoint, hurricanes and tornadoes are examples of environmental vorticity, requiring interdisciplinary, nonlinear studies for their comprehension. Appropriate mathematical models comprise a set of nonlinear hydrodynamic and thermodynamic equations, and for hurricanes it is crucial to account for the Earth's rotation through the Coriolis force. Although a wide network of meteorological stations exists and available models provide some useful insights, the detailed modeling and prediction of hurricanes and tornadoes remains an

exciting challenge for future practitioners of nonlinear science.

HUYGENS PRINCIPLE

Huygens principle (HP) is a notion that goes back to the classical *Traité de la Lumière* (Treatise on Light) by Christiaan Huygens, which was published in 1690. In its original meaning, HP gives the following geometric description of the wave fronts. Consider a wave front at the moment t as the source of the new (secondary) waves emanating from points of this front. HP states that the new wave front at a later time is the envelope of the fronts of these secondary waves (see Figure 1). This principle was further elaborated by Augustin Fresnel who added the superposition principle for the amplitudes of the secondary waves to explain the phenomenon of diffraction.

In the second half of the 19th century, various mathematical aspects of the HP were discussed in the pioneering works of Gustav Kirchhoff, Eugenio Beltrami, and Vito Volterra. At the same time it, became evident that different authors were using the term *Huygens principle* with different meanings. It was Jacques Hadamard who brought clarity in this area. In his fundamental "Lectures on Cauchy's Problem" published in 1923, Hadamard introduced the notion of the "Huygens principle in the narrow sense" (minor premise) (Hadamard, 1923). In physical language one can formulate this principle in the following way: *an instantaneous signal remains instantaneous for every observer at each later time*. This property implies that a localized disturbance will have an effect localized

Figure 1. Diagram related to Huygens' principle.

in time at any point (for example, for sound waves after some time there will be complete silence).

Mathematically, HP in the narrow sense means that the fundamental solution of the corresponding hyperbolic equation vanishes not only outside but also inside the characteristic conoid and, thus, must be located on it. Equivalently, a hyperbolic equation satisfies the HP in the narrow sense if the solution of the Cauchy initial-value problem at a point P depends not on all the Cauchy data, but only on its part on the intersection of the characteristic conoid with vertex P with the Cauchy surface.

In contrast to the original principle ("major premise" in Hadamard's terminology), which holds for a general class of wave propagations, HP in the narrow sense is actually a remarkable property valid only for very special equations. In particular, this never happens in two dimensions, where one has wave diffusion. One can see this when a pebble falls in water, where the front wave is followed by the so-called "residual waves," and any object on the water surface is hit by the subsequent waves many times.

To explain this phenomenon, consider the fundamental solution of the wave equation

$$\left(\frac{\partial^2}{\partial t^2} - \frac{\partial^2}{\partial x_1^2} - \dots - \frac{\partial^2}{\partial x_n^2} \right) \Phi = 0,$$
$$\Phi(x, 0) = 0, \quad \frac{\partial \Phi}{\partial t}(x, 0) = \delta(x).$$

This solution has the form

$$\Phi = \frac{1}{2\pi} \frac{\theta(t^2 - |x|^2)}{\sqrt{t^2 - |x|^2}}$$

when $n = 2$, and

$$\Phi = \frac{1}{2\pi} \delta(t^2 - |x|^2)$$

when $n = 3$. Here θ is the Heaviside step-like function and δ is the Dirac delta-function. Thus, we see that indeed for $n = 3$, Φ is located on the characteristic cone $t^2 - |x|^2 = 0$, which explains the sharpness of signal transmission in our three-dimensional world, while in two dimensions this is not the case.

Corresponding formulas for the solutions of the Cauchy problem for the wave equation in two and three spatial dimensions were found by Simeon Poisson and Kirchhoff, and for general n by Orazio Tedone. From these formulas it follows that for the Euclidean spaces, the HP in the narrow sense holds in all odd dimensions starting from 3 and never holds in even dimensions.

Hadamard raised the question of how to describe all second-order hyperbolic equations that satisfy the HP in the narrow sense (*Hadamard's problem*). Hadamard found a criterion for this, but it was not effective enough to answer this question. There was a common belief

that the HP in the narrow sense holds only for the wave equations in the Euclidean spaces of odd dimensions until 1953 when Karl Stellmacher found other examples (Stellmacher, 1953). He showed that the hyperbolic equation

$$\left(\frac{\partial^2}{\partial t^2} - \frac{\partial^2}{\partial x_1^2} - \cdots - \frac{\partial^2}{\partial x_n^2} + \frac{m(m+1)}{x_1^2} \right) \phi = 0$$

with integer nonnegative m satisfies the HP in the narrow sense if the dimension n is odd and large enough: $n \geq 2m + 3$.

Later in 1967–68, Stellmacher and Lagnese solved the Hadamard problem in the class of the hyperbolic equations of the special form

$$\left(\frac{\partial^2}{\partial t^2} - \frac{\partial^2}{\partial x_1^2} - \cdots - \frac{\partial^2}{\partial x_n^2} + u(x_1) \right) \phi = 0,$$

when the potential depends only on one of the coordinates. They showed that the corresponding potentials are rational and (in modern terminology) can be described as the results of the Darboux transformations applied to $u=0$ (Lagnese & Stellmacher, 1967).

The first examples of the Huygensian potentials $u(x)$ depending on more than one coordinate were found in 1993 by Berest and Veselov, who discovered a close relation of the Hadamard problem with the theory of quantum integrable systems of Calogero–Moser type (Berest & Veselov, 1994; Chalykh et al., 1999).

For the hyperbolic equations on the manifolds with nontrivial metrics, the Hadamard problem is still open even when the number of spatial variables is three. There are known only several particular cases when HP in the narrow sense is satisfied, including the modified wave equation on the symmetric spaces with even multiplicities, in particular on the spheres (Lax & Phillips, 1978) and simple compact Lie groups (Helgason, 1984), and wave equations on the spaces with the plane wave metrics (Günther, 1965). For a review of the results on the HP for other relativistic wave equations (e.g., Maxwell's equations), see Günther (1988).

Because the HP in the narrow sense is a very rare phenomenon, it is natural to ask about a weaker version. Such a version called the “generalized Huygens’ principle” was introduced by Lax and Courant and is valid for a general hyperbolic equation. It states that the singularities of the solution at the point P depend only on the singularities of the initial data and only so far as these data are presented on the characteristic conoid of P . This implies that “in an approximate, and for that matter, usually satisfactory, sense any hyperbolic system does preserve the sharp signals, though in general slightly blurred” (Courant & Hilbert, 1962).

Finally, one should mention that the theory of HP is closely related to the deep theory of lacunae in the domains of dependence of hyperbolic equations (Petrovskii, 1945; Atiyah et al., 1970, 1973).

HYDROGEN BOND

The hydrogen bond is a weak chemical bond, which nevertheless is fundamentally important in stabilizing secondary structure motifs in biological macromolecules such as proteins and DNA. Also, the peculiar properties of liquid water are attributed to a complex hydrogen bond network between neighboring water molecules. A hydrogen bond is mediated by a proton sitting in between two negatively charged atoms, the more negative of which is called the hydrogen bond donor and the other the hydrogen bond acceptor. Figure 1a shows a prototype hydrogen bond, using the N–H and the C=O group of two peptide units in an α -helix as an example (one of the most important secondary structure motif of proteins).

Hydrogen bonding leads to a dramatic distortion of the potential energy surfaces that determine the nuclei positions, giving rise to strongly anharmonic or even double-well potentials. Much of our knowledge about hydrogen bond potentials stems from vibrational spectroscopy, see, for example, Pimentel & McClellan (1976); Hadzi & Bratos (1976); Henri-Rousseau & Blaise (1998). The absorption band of the high-frequency vibration of the donor-proton bond (i.e., the NH bond in the example considered here) changes considerably upon formation of a hydrogen bond. The most evident effects are a strong red-shift with respect to the free group, an intensity increase and band broadening, often accompanied by a peculiar band shape with rich substructure. These effects could be reasonably explained using a model of the electronic (ground state) potential energy surface as a function of two coordinates, the high-frequency N–H stretching coordinate q , and the low-frequency hydrogen bond coordinate Q (see Figure 1a). A Taylor expansion of that potential energy surface yields (Hadzi & Bratos, 1976; Henri-Rousseau & Blaise, 1998)

$$V(Q, q) = \frac{1}{2}m\omega^2 q^2 + \frac{1}{2}M\Omega^2 Q^2 + \chi' Q q^2 + \dots, \quad (1)$$

where the first two terms represent the harmonic normal modes of the N–H stretching and the hydrogen bond vibration with oscillation frequencies ω and Ω and effective masses m and M , respectively. Typical vibrational frequencies of N–H stretching modes lie in the range of $\omega = 3000\text{--}3600\text{ cm}^{-1}$, while hydrogen bond vibrations are found around $\Omega = 50\text{--}300\text{ cm}^{-1}$, depending on the masses of the molecular groups involved. This translates into typical spring constants of $k_{\text{N-H}} \approx 650\text{ N/m}$ for the N–H bond and $K_{\text{N-O}} \approx 10\text{--}20\text{ N/m}$ for the hydrogen bond. In the case of most molecular systems, the harmonic approximation is extremely good, and higher order terms in Equation (1) can be treated as weak perturbation (being responsible, for example, for energy dissipation). Harmonic normal modes have the property to decouple completely. Linear

Figure 1. (a) A prototype hydrogen bond. The discussion presented here applies for other hydrogen bonds in essentially the same way. (b) Potential energy surfaces of the $v_{\text{NH}} = 0$ and the $v_{\text{NH}} = 1$ level.

phenomena, such as propagation of linear phonon wave packets, can be fully understood in the harmonic approximation.

However, one of the striking features of hydrogen bonds is an extraordinarily large anharmonicity, described by third, and higher, order terms in the expansion Equation (1). This anharmonicity leads to appreciable nonlinear behavior, a property that makes hydrogen-bonded crystals interesting objects to study in nonlinear science.

The problem can be simplified significantly when taking into account the more than one order of magnitude difference in the N–H and the hydrogen bond vibration frequency, allowing an adiabatic separation of timescales to be introduced. This is done in exactly the same way as the Born–Oppenheimer approximation separates off the fast motion of the electrons from the slow motion of the nuclei. In the case of a hydrogen bond, the motion of the fast N–H vibration adiabatically adapts to the position of the coordinate Q of the hydrogen bond. When the coordinate Q is held fixed, one can recast Equation (1) in the form

$$V(Q, q) = \frac{1}{2}m\omega_{\text{eff}}^2 q^2 + \frac{1}{2}M\Omega^2 Q^2 \quad (2)$$

with

$$\omega_{\text{eff}} \approx \omega + \frac{\chi'}{m\omega} Q \equiv \omega + \chi Q. \quad (3)$$

In this approximation, the vibration frequency of the N–H stretching mode, and hence its excitation energy, varies linearly with the hydrogen bond distance Q . The other third-order term not considered in Equation (1) ($\sim Q^2 q$) leads to a Q -dependent shift of the N–H bond-length without change of its excitation energy. Such a linear dependence is observed experimentally for a large variety of hydrogen-bonded crystals (Pimentel & McClellan, 1976), which allows direct measurement of the nonlinear coupling constant: $\chi_{\text{N-H}} \approx 500\text{--}1500\text{ cm}^{-1}/\text{\AA}$ or

$\chi_{\text{N-H}} \approx 1-3 \times 10^{-10}$ N. The nonlinear coupling constant varies significantly with hydrogen bond type.

Starting from Equations (2) and (3), one can construct potential energy surfaces (see Figure 1b), leading to the displaced oscillator picture that is well known from electronic Franck–Condon transitions. However, keep in mind that all this is happening on the *electronic ground state* potential surface! Each potential energy surface corresponds to a vibrational excitation level $v_{\text{N-H}} = 0, 1, \dots$ of the N–H stretching mode, and describes the total energy of the system as a function of the hydrogen bond coordinate Q . It is the nonlinear coupling term χ that gives rise to the displacements of the potential energy surfaces. The reorganization energy λ , that is, the energy the system gains by relaxation towards the bottom of excited state potential energy surface after a vertical “Franck–Condon”-like excitation (see Figure 1b), is given by

$$\lambda = \frac{\chi^2}{2M\Omega^2} = \frac{\chi^2}{2K_{\text{N-H}}}. \quad (4)$$

Biological macromolecules, such as proteins and DNA, often form one-dimensional quasicrystals with approximate translational symmetry, whose structures are stabilized by hydrogen bonds. This observation motivated Alexander Davydov to speculate about nonlinear collective phenomena in bio-macromolecules (Davydov, 1979). Davydov discussed only the C=O vibration in a N–H $\cdots$ OC-hydrogen bond, which shows the same phenomenon with a smaller, yet still appreciable, nonlinearity $\chi_{\text{CO}} \approx 300 \text{ cm}^{-1}/\text{\AA}$ or $\chi_{\text{CO}} \approx 6 \times 10^{-11}$ N (Careri et al., 1984). Dipole–dipole interaction between adjacent C=O and N–H vibrations tends to delocalize the excitation along the crystal, forming a vibrational exciton (vibron). Coupling of the vibron to lattice-deformation modes, mediated through the nonlinearity χ of the hydrogen bonds, subsequently self-localizes the excitation. The hydrogen bond is getting stronger after excitation of the high frequency vibration (see Figure 1b), leading to a contraction of the macromolecular backbone. As a result, solitons and/or polarons may be formed.

HYDROTHERMAL WAVES

Hydrothermal waves are traveling waves produced by a supercritical instability of the thermocapillary flow of a thin liquid layer with a free surface subjected to a horizontal temperature gradient.

This article presents experiments in one spatial dimension, then gives some indications about the physical basis for wave effects. Extended systems are then considered and applications are described.

Experimental Observation in One Spatial Dimension

Hydrothermal waves were first experimentally observed in hot-wire convection experiments (Vince & Dubois, 1992), and a geometrically simpler system was then imagined by Daviaud & Vince (1993) that led to the first clear experimental observation of hydrothermal waves.

The classical experiment is as follows: a channel whose long sides are thermoregulated copper blocks contains a fluid with free surface. Its typical section is depicted in Figure 1. The horizontal gradient of temperature on the free surface leads to a gradient of surface tension. This results in a stationary flow of the surface from the hot side (low surface tension) toward the cold side (high surface tension): this is the Marangoni effect. Due to mass conservation, there is a return flow in the bottom of the layer. This is the basic thermocapillary flow (Kuhlman, 1999; Schatz & Neitzel, 2001), the instability of which leads to hydrothermal waves (Smith & Davis, 1983; Davis, 1987). A similar flow is present in the melted wax of a candle (the cold side being the external boundary and the hot side being the wick). For visualization purposes, silicon oil is used because it is transparent and allows shadowgraphy.

For fluid depth h larger than the capillary length λ_c , one observes first when increasing the temperature gradient corotative rolls with their axis parallel to the cold and hot side of the container. Then hydrothermal waves of type 1 (HW1, plane waves) appear on top of the rolls (Figure 2a) (Riley & Neitzel, 1998). HW1 are emitted by “line”-sources that extend over the whole extension between the hot and the cold sides. For smaller depth $h < \lambda_c$, waves of type 2 (HW2) are observed (Figure 2b,c); they are circular and emitted by point sources located on the cold side of the container (Burguete et al., 2001; Garnier & Chiffaudel, 2001).

When the fluid depth is even larger (typically larger than the depth λ_{th} for which thermocapillary

Figure 1. Thermocapillary basic flow created by Marangoni effect and susceptible to instability into hydrothermal waves. Left: the melted wax below the flame of a candle is an example of thermocapillary flow. Right: typical section of a laboratory setup. A horizontal temperature gradient is applied to a thin liquid layer with a free surface. Hydrothermal waves (not drawn) will propagate in the horizontal direction orthogonal to the temperature gradient ∇T , and with a small component along the gradient.

Figure 2. Shadowgraphic images of hydrothermal waves in rectangular cells. (a): $L_x = 30$ mm, $L_y = 180$ mm, $h = 2.75$ mm, $\Delta T = 7$ K. A single right-going wave of type 1 is present. The left side is a source, the amplitude of the wave is weak, and stationary corotative rolls orthogonal to the gradient are present. (b): $L_x = 30$ mm, $L_y = 180$ mm, $h = 1$ mm, $\Delta T = 7.3$ K. (c): $L_x = 30$ mm, $L_y = 90$ mm, $h = 1$ mm, $\Delta T = 5$ K. Hydrothermal waves of type 2, with a source located at the center of the cold side of the channel.

forces balances thermogravity forces), hydrothermal wave instability is replaced by a stationary instability: parallel rolls with axis aligned with the temperature gradient.

Physical Mechanisms

Vertical Temperature Gradient: Bénard–Marangoni Instability

Pearson (1958) gave a simple mechanism to explain hexagon formation in Bénard–Marangoni convection. In that case, the temperature gradient is purely vertical (cold at the surface, and hot at the bottom) and the velocity of the fluid is zero before the instability. Let us consider a positive temperature perturbation at the surface of the fluid: a point has a temperature larger than its surroundings. Because surface tension decreases with temperature for simple fluids, the surface tension is smaller at that point. This implies a differential stress on the free surface, and according to the equations of

motion, the fluid has to flow away from that point (fluids flow from regions of small surface tension toward regions of large surface tension). But due to mass conservation, some fluid must rise up from the bulk of the fluid to the point on the surface (in the same way that wax climbs around the wick and flows away on the surface towards cooler regions). This ascending fluid is at a higher temperature because of the vertical temperature gradient. In conclusion, any positive temperature perturbation at the free surface is amplified; this means that there is an instability, namely, the Bénard–Marangoni instability into stationary hexagons, as can be shown by a linear stability analysis.

Horizontal Temperature Gradient: Hydrothermal Waves

Basically, the mechanism is the same, but one has to take into account, first, that the basic flow has

Figure 3. Top three pictures: extended patterns: single HW1 ($h = 1.9$ mm, $\Delta T = 14.25$ K), HW1 and HW2 together ($h = 1.2$ mm, $\Delta T = 20$ K), turbulent HW1 ($h = 1.9$ mm, $\Delta T = 25$ K). Bottom three pictures: localized patterns: HW2 ($h = 1.2$ mm, $\Delta T = 10$ K), inverted spirals ($h = 1.2$ mm, $\Delta T = -9$ K), and flowers ($h = 1.9$ mm, $\Delta T = -7$ K).

a finite velocity (see Figure 1), and second, that the vertical temperature profile is nonmonotonous. This intricacy results in a time-dependent pattern, in contrast to the stationary hexagons described above. Time-dependence is due to the existence of two different timescales: one for the relaxation of thermal perturbations (depending on the thermal diffusion coefficient) and the other for the relaxation of velocity perturbations (depending on kinematic viscosity). The ratio of those two timescales is called the Prandtl number, Pr .

Smith (1988) expressed two different tentative mechanisms depending on Pr in the limit cases of a flow dominated by inertial effects ($Pr \rightarrow 0$) or by viscous effects ($Pr \rightarrow \infty$). The relaxation of temperature and velocity perturbations then occur on very different timescales. Depending on the signs of the temperature and velocity gradients, an oscillatory behavior is shown to be unstable and to propagate along the horizontal temperature gradient (small Pr), or perpendicularly to it (large Pr).

Finally, note that hydrothermal waves are not necessarily associated with surface deflections (in contrast to gravity waves for example): they are an instability mode of the temperature field in the bulk (Pelacho & Burguete, 1999).

Experiments in 2-d

Recent experiments in extended geometries (the two horizontal dimensions are large compared to the fluid height) revealed a large variety of hydrothermal waves instability modes. Several of these obtained in cylindrical geometry (the candle geometry) are reproduced in Figure 3. The control parameter is defined as $\Delta T = T_{\text{ext}} - T_{\text{int}}$. This quantity can be positive or negative, and both cases are not equivalent. This is due to the presence of curvature (Garnier & Normand, 2001) that may also localize patterns near the center.

Applications

Many technological applications in which the Marangoni effect is present will involve hydrothermal waves—even when manufacturing is carried out in low gravity, where gravity-dependent, buoyancy-driven flow is reduced, for example, floating zone purification of silicon crystals, photographic films production, and melting of metals. In all of these processes, the aim is to avoid hydrothermal waves, which are detrimental to the final product, for example, by reducing the homogeneity of crystals.

In the physics laboratory, hydrothermal waves represent an ideal experimental nonlinear waves system. They are well modeled by a complex Ginzburg–Landau equation (Garnier et al., 2003) and can be used as a robust model for the study of the transition to spatiotemporal chaos. For example, as their group velocity is finite, they are subject to the convective/absolute distinction. Modulated amplitude waves have also been reported.

HYSTERESIS

The word *hysteresis* is derived from the Greek where it meant “shortcoming.” In the present physical context it describes a retardation effect when the forces acting upon a body are changed. In particular, in magnetism hysteresis represents a lagging in the values of the net magnetization in a magnetic material due to a changing magnetizing field. In general, hysteresis signifies the history of dependence of physical quantities in systems responding to changes in external conditions. The term is most commonly, but not exclusively, applied to magnetic materials; for example, there is a class of metals called shape memory alloys that can be bent or stretched plastically over large distances back and forth many times without hardening.

Consider a ferromagnetic material that is originally unmagnetized. As the external magnetic field (H) is increased, the induced magnetization (M) also increases. The induced magnetization eventually saturates. Now, if the external field is reduced, the induced magnetization also is reduced, but it does not follow the original curve. Instead, the material retains a certain permanent magnetization called the remanent magnetization M_r when $H=0$. The remanent magnetization is the permanent magnetization that remains after the external field is removed. If the external field is reduced more, the remanent magnetization will eventually be removed. The external field applied in the opposite direction for which the remanent magnetization goes to zero is termed the coercivity H_c . The product of M_r and H_c is termed the strength of the magnet. As the external field continues to reverse, permanent magnetization of the opposite polarity is created in the magnet. A similar curve is traced for the negative direction with saturation, remanent magnetization and coercivity. The hysteresis curve then retraces the previous points as the field cycles, and the shape of the loop after the first cycle is roughly the same as after many cycles. Note that the area under the hysteresis loop corresponds to the work done on the system by an external field that reorients the magnetization in a single cycle.

When an electric field (E) is applied to a ferroelectric crystal, the domains that are favorably oriented with respect to this field grow in size at the expense of those that are misaligned. In addition, favorably oriented domains may nucleate and grow until the whole crystal becomes one domain. The relation between

the resulting polarization P and E is described by a hysteresis loop in analogy to the relationship between M and H for ferromagnets.

Suppose now, in general, that the system under consideration can be described by a macroscopic order parameter η . Under the influence of an external field σ coupled linearly to η , the state of the system is determined by an equation of state that expresses a minimum condition of the associated thermodynamic potential V . Assuming the presence of at least one control parameter leads directly to the problem of catastrophes, an area investigated by René Thom. The cusp catastrophe is described by the potential

$$V(\eta) = \frac{\varepsilon}{4}\eta^4 + \frac{1}{2}a\eta^2 - \sigma\eta, \tag{1}$$

where a is a control parameter. This potential describes second-order phase transitions both in the absence ($\sigma = 0$) and in the presence ($\sigma \neq 0$) of external fields as proposed by Lev Landau. The butterfly catastrophe, on the other hand, is described by

$$V(\eta) = \frac{1}{6}\eta^6 + \frac{a}{4}\eta^4 - \frac{b}{3}\eta^3 + \frac{c}{2}\eta^2 - \sigma\eta \tag{2}$$

and has been used to model first-order phase transitions.

To illustrate the related phenomenon of hysteresis we first investigate the bifurcation effect by minimizing Equation (1), which yields the equation of state

$$\varepsilon\eta^3 + a\eta = \sigma. \tag{3}$$

A transition between a single stable solution for $a > 0$ and a bistable situation for $a < 0$ takes place when $a = 0$. However, a new feature is the phenomenon of external-field-induced hysteresis and metastability. Stability corresponds to a solution for which $\partial^2 V / \partial \eta^2 > 0$ and, if more than one solution exists that is stable, we call the higher energy solutions metastable. Figure 1 shows the difference in the response of the order parameter to the application of an external field. In unstable situations, η as a function of σ is a smooth single-valued function. Multistability results in multi-valuedness in some ranges of the external fields. Figure 1c demonstrates the regions of multistability in the parameter space. The dividing line in the cusp catastrophe case is given by the equation

$$-4a^3 + 27\sigma^2 = 0. \tag{4}$$

This indicates the parameter set for which a triple solution of the cubic equation in (4) is obtained. Figure 2 is an extension of these concepts to the butterfly catastrophe case that exhibits thermal hysteresis (if the control parameter a involves a temperature dependence) and a double hysteresis under the influence of an external field.

Figure 1. The order parameter's response to an externally applied field (a) in a unistable state, (b) in a bistable state (hysteresis), and (c) separation of the control parameter space into solution's multiplicity regions.

Figure 2. (a) Bifurcation plot (thermal hysteresis) and, (b) double field-induced hysteresis in the butterfly catastrophe case.

The sixth power free energy expansion for the order parameter η

$$F = F_0 + a\varepsilon\eta^2 + A_4\eta^4 + A_6\eta^6 - h\eta \quad (5)$$

has been widely used to model first-order phase transitions provided $A_4 < 0$. The equation of state gives the order parameter in equilibrium

$$\eta_0 = \left\{ \left[-A_4 - (A_4^2 - 3a\varepsilon A_6)^{1/2} \right] / 3A_6 \right\}^{1/2}. \quad (6)$$

The transition temperature is

$$T_c^* = T_c + \frac{A_4^2}{4aA_6}, \quad (7)$$

where $\varepsilon = T - T_c$, and the disordered phase ($\eta = 0$) terminates its stability at $T = T_c$ while the ordered one (η_0) does so at $T = T_0^*$, where

$$T_0^* = T_c + \frac{A_4^2}{3aA_6}. \quad (8)$$

Importantly, the existence of a thermal hysteresis phenomenon is associated with first-order phase transition. Thermal hysteresis means that on cooling, the disordered phase is stable below the equilibrium transition temperature, while on heating, the ordered phase is stable above it. The associated effects are called supercooling and superheating, respectively.

IDEMPOTENT ANALYSIS

Definition and Introduction

The analyses that we all know and use (differentiation, integration, Fourier analysis, matrix analysis, etc.) are tacitly based on algebra defined by means of the conventional operations: addition, multiplication, and their inverses. In idempotent analysis, the starting point is not conventional algebra but instead the idempotent semiring.

Definition 1. A semiring is a set $\mathcal{D}$ with two binary operations, $\oplus$ (called “sum” or “addition”) and $\otimes$ (called “product” or “multiplication”) and two specific elements ε and e such that

- $(\mathcal{D}, \oplus, \varepsilon)$ is a commutative monoid with identity element ε ,
- $(\mathcal{D}, \otimes, e)$ is a monoid with identity element e ,
- $a \otimes \varepsilon = \varepsilon \otimes a = \varepsilon$, for all $a \in \mathcal{D}$,
- $a \otimes (b \oplus c) = (a \otimes b) \oplus (a \otimes c)$, for all $a, b, c \in \mathcal{D}$.

The semiring is called idempotent if in addition

- $a \oplus a = a$, for all $a \in \mathcal{D}$.

The semiring is called commutative if

- the multiplication $\otimes$ is commutative.

A monoid here is a set of elements with one operation. An idempotent semiring is sometimes referred to as a “dioid,” which means “twice a monoid.” It is the property $a \oplus a = a$ that distinguishes a dioid from conventional algebra. The most well-known example of a dioid is the so-called max-plus algebra, where $\mathcal{D} = \mathbb{R} \cup \{-\infty\}$, the $\oplus$ operation is the maximum, with identity element $\varepsilon = -\infty$, and the $\otimes$ operation is (conventional) addition, with the identity element $e = 0$. As a numerical example, $5 \otimes (3 \oplus -2) = 8$. A noticeable difference between max-plus algebra and conventional algebra is that linear equations do not always have a solution (e.g., what is x in $5 \oplus x = 4$?). Addition is not cancellative in the sense that $a \oplus b = a \oplus c$ does not in general imply $b = c$.

The pioneering work in the max-plus algebra is Cuninghame-Green (1979), which has been extended into a system-theoretic direction in Baccelli et al. (1992). The phrase *idempotent analysis* was coined by Kolokoltsov & Maslov (1997). In Gunawardena (1998), it is shown that idempotency shows up in many different areas of mathematics; Gunawardena (1998, pp. 1–49) is an excellent survey. Applications are described in Le Boudec & Thiran (2001); and Heidergott et al. (2004).

We choose the max-plus algebra setting to introduce some analysis. Consider the recurrence relation

$$x(k+1) = A \otimes x(k), \quad (1)$$

which represents a model with state $x \in \mathbb{R}^n$ and where A is an $n \times n$ matrix with elements a_{ij} . More explicitly, this relation is defined by its component-wise writing

$$\begin{aligned} x_i(k+1) &= \bigoplus_j (a_{ij} \otimes x_j) = (a_{i1} \otimes x_1) \\ &\quad \oplus (a_{i2} \otimes x_2) \oplus \cdots \oplus (a_{in} \otimes x_n), \\ i &= 1, 2, \dots, n. \end{aligned}$$

The conventional way of writing this would be $x_i(k+1) = \max_j (a_{ij} + x_j)$. Such a model is sometimes referred to as a discrete event dynamic system.

If $x(0)$ is an eigenvector of A in the max-plus algebra defined as

$$A \otimes x(0) = \lambda \otimes x(0), \quad (2)$$

equivalently written as $\max_j (a_{ij} + x_j(0)) = \lambda + x_j$, with not all components $x_i(0)$ equal to ε , and where λ is called the eigenvalue, then $x_i(k+1) = \lambda + x_i(k) = x_i(0) + (k+1)\lambda$. The new state is obtained by adding λ to the previous state. In graph-theoretic terms, λ can be characterized as follows.

Theorem 1. If the square matrix A is irreducible, equivalently, its corresponding graph is strongly connected and, there exists one and only one eigenvalue (with possibly several eigenvectors). This eigenvalue is equal to the maximum cycle mean of the graph:

$\lambda = \max_{\zeta} |\zeta|_w / |\zeta|_l$, where ζ ranges over the set of circuits in the graph, where $|\zeta|_l$ is the number of arcs of ζ and $|\zeta|_w$ its weight, that is, the addition of all a_{ij} which correspond to arcs of ζ .

This theorem is referred to as the spectral theorem. A practical interpretation for this model and analysis is given below.

Examples

The first example of a dioid already encountered is $R \cup \{-\infty\}$ with $\oplus$ as max and $\otimes$ as addition. Other examples are:

- The set of $n \times n$ matrices with $A \oplus B$ and $A \otimes B$ defined as $\{A = \{a_{ij}\}, B = \{b_{ij}\}\}$

$$\begin{aligned} \{A \oplus B\}_{ij} &= \max(a_{ij}, b_{ij}), \{A \otimes B\}_{ij} \\ &= \max_k (a_{ik} + b_{kj}). \end{aligned}$$

- The set $R \cup \{-\infty\}$ with min as $\oplus$ and addition as $\otimes$ is isomorphic to the max-plus algebra.
- The set $R \cup \{-\infty\} \cup \{+\infty\}$ with $\oplus$ defined as max and $\otimes$ as min.
- The set $\{0, 1\}$ with $\oplus$ defined as max and $\otimes$ as min.
- The set $\{0, 1\}$ with $\oplus$ defined as max and $\otimes$ as min.
- The set of all subsets of the R^2 plane, including $\emptyset$ and the whole R^2 itself, with $\oplus$ defined as $\cup$ and with $\otimes$ defined as the vector sum of subsets.
- Extension to polynomials or formal power series by defining (a polynomial or formal power series is given by $f(z) = \bigoplus_{k=0,1,\dots} f_k z^k$):

$$\begin{aligned} f \oplus g : (f \oplus g)_k &= f_k \oplus g_k; f \otimes g : (f \otimes g)_k \\ &= \max_{i+j=k} f_i \otimes g_j. \end{aligned}$$

Relation to Nonlinear Theory and Practice

One must be careful using the word *nonlinear*. System (2) for instance is nonlinear with respect to conventional algebra, but it is considered linear in the max-plus algebra.

Relationship with Other Mathematical Disciplines

An interpretation in graph-theoretic terms is often possible. The occurrences of events in timed event graphs, the latter forming a subclass of Petri nets, can be modeled by means of an equation of the form (1). If $x \in R^n$, define $\|x\|$ to be its l^∞ norm, that is, $\|x\| = \max_i |x_i|$. A mapping $f : R^n \rightarrow R^n$ is called non-expansive if $\|f(x) - f(y)\| \leq \|x - y\|$. As an example, $f(x) = A \otimes x$ is non-expansive. An important theme is the study of periodic solutions of non-expansive mappings; that is, does λ exist such that $f^k(x) = k\lambda + f(x)$? Another theme is that of the finiteness of the transient behavior (before one reaches a periodic behavior), if one starts with an arbitrary initial condition.

Some Applications

Consider the system (2). Interpret a_{ij} as the traveling time of a train on a track (if existing) between departure station j and arrival station i . Quantity $x_i(k+1)$ refers to the earliest departure time of trains at station i that depart for the $(k+1)$ th time. The model states that in order to depart (for the $(k+1)$ th time), the train must wait until all trains, which departed for the k th time, have arrived; $\max_j (a_{ij} + x_j)$ reflects the maximum of all arrival times. This allows passengers to change trains (one could add some minutes to all a_{ij} to account for the changeover times). If a track between two stations, say l and m , does not exist, set $a_{ml} = \varepsilon$. If one assumes that the departures take place as soon as possible subject to the restriction of passengers changing over, then the model $x(k+1) = A \otimes x(k)$, with an initial condition $x(0)$, determines all future departure times. If this $x(0)$ is an eigenvector, then one has a timetable with constant interdeparture times, this constant being λ . This constant is a lower bound for the interdeparture times of any periodic timetable obeying the changeover rule.

In the above, trains can be viewed as discrete flows on networks. If one replaces "trains" by "messages" and "all railway tracks" by "computer network" or "internet," one enters another field of application that has been described and analyzed in Le Boudec & Thiran (2001).

In discrete-time optimal control theory, or in decision processes on Markov chains, one encounters the equation

$$V(k, x) = \max_u (V(k+1, f(x, u)) + g(x, u)),$$

which is a consequence of Bellman's principle of optimality. The underlying model is $x(k+1) = f(x(k), u(k))$, and the costs during step k are $g(x(k), u(k))$. The function V is the value function. This equation, with the operations of addition and maximization can be interpreted and analyzed in the max-plus algebra sense (Akian et al., 1998). Applications in automata theory can also be found in Gunawardena (1998).

INCOHERENT SOLITONS

Until 1996, solitons were considered to be exclusively coherent entities. However, experimental observations of self-trapping of partially spatially incoherent light (Mitchell et al., 1996) and of white light (Mitchell et al., 1997) in photorefractive media have shown that incoherent beams can also form solitons (Figure 1). These solitons are multimode or speckled beams for which the instantaneous intensity distribution varies randomly in space and/or time. They can exist only in non-instantaneous media whose response time is much longer than the random fluctuation time across the incoherent beam. Such a medium responds to the time-averaged envelope and not to the instantaneous speckles that constitute the incoherent beam. An incoherent soliton forms when the time-averaged intensity induces a multimode wave and traps itself in the waveguide by populating the guided modes in a self-consistent fashion. These random-phase and weakly correlated self-trapped entities exhibit a host of unique properties that have no analog in the coherent regime. Moreover, their existence is related to many other areas of physics, in which nonlinearities, stochastic behavior, and statistical averaging are involved. For example, incoherent modulation instability effects and incoherent pattern formation relate to many systems in nature: from clustering in a cooled atomic gas to self-supported "stripes" of electrons in semiconductors, from high- T_c superconductors to structures in fluids and gravitational effects.

Figure 1. Self-trapping of spatially and temporally incoherent white light from an incandescent light bulb.

Numerous theoretical and experimental works followed the pioneering experiments (see Segev & Christodoulides (2001) and references within). This rapid progress in the area of incoherent solitons offers a number of interesting fundamental ideas as well as possible applications. For example, coherence engineering can be used to control modulation instabilities and to create interesting stable patterns in nonlinear materials for various applications. There is also an exciting possibility of using self-trapped light beams from incoherent sources, such as light-emitting diodes, for creating reconfigurable optical interconnects and beam steering.

Several theories have been developed to describe the propagation of partially incoherent beams and soliton formation in noninstantaneous nonlinear materials (Segev & Christodoulides, 2001). These include the coherent density theory (Christodoulides et al., 1997), the modal theory (Mitchell et al., 1997), and the mutual coherence theory (Shkunov & Anderson, 1998). Other, more approximate theories relying on ray optics (Snyder & Mitchell, 1998) and on the Wigner distribution (Hall et al., 2002) have also been suggested. The first three approaches are rather complete and equivalent to one another (Christodoulides et al., 2001). Here, we briefly overview the two most widely used theories.

Coherent Density Theory

The coherent density method is a dynamic approach suited for studying the evolution dynamics of incoherent solitons, their interactions, instabilities, and correlation statistics. In this formalism, the incoherent field is described by means of a so-called coherent density function, from which one can deduce the optical intensity distribution as well as the associated correlation statistics. Mathematically, the self-trapping process is described by an infinite set of nonlinear Schrödinger-like equations, provided that each coherent component at the input is appropriately weighted with respect to the incoherent angular power spectrum of the source (Christodoulides et al., 1997). These equations can be solved numerically by using modified beam propagation procedures.

Modal Theory

The modal theory is currently widely considered as the method of choice in terms of identifying static incoherent solitons, their range of existence, and correlation properties. The fundamental requirements of incoherent self-trapping were the starting point of this formulation. Incoherent solitons are identified by solving the underlying coupled (stationary) nonlinear Schrödinger-like equations in a self-consistent fashion (Mitchell et al., 1997). To solve these equations self-consistently, one needs to start with an arbitrary index profile, then solve for the guided modes and sum them incoherently to get the intensity profile, and finally

use this intensity profile to calculate the new induced-index profile. This process should be repeated until the solutions are stationary. The stationary solutions give the incoherent soliton intensity profile as well as its modal distribution and statistical properties.

1-d and 2-d Dark Incoherent Solitons

The existence of dark incoherent solitons and requirements for their observations were predicted (Coskun et al., 1998) two years after the observation of bright incoherent solitons. Such dark incoherent solitons were experimentally observed soon thereafter (Chen et al., 1998). In that experiment, (1 + 1)-dimensional dark incoherent solitons were observed, along with the self-trapping of a (2 + 1)-d dark incoherent beam. That is, a self-trapped 2-d void nested in spatially incoherent beam was demonstrated (Chen et al., 1998). As in the coherent case, fundamental dark incoherent solitons were found to exist only in defocusing nonlinear media and to require an initial transverse phase shift at the center of the dark stripe. 2-d dark incoherent solitons were initiated from a vortex beam that was generated by replacing a step mirror with a helicoidal phase mask, which created an optical vortex of unit topological charge. For bright solitons, only guided modes (bound modes) are self-trapped, whereas dark incoherent solitons involve a belt of radiation modes (unbound states). Unlike their coherent counterparts, fundamental dark and vortex solitons were always found to be gray because of the presence of both odd and even radiation modes at the center of the notch (Christodoulides et al., 1998). Furthermore, the grayness depends on the coherence length of the carrier beam. Dark soliton splitting and "phase memory" effects were also observed theoretically and experimentally (Coskun et al., 1999).

Modulation Instability, Pattern Formation, and Soliton Clustering

Both theory and experiment have revealed that modulation instabilities can take place with incoherent light beams provided that the nonlinearity exceeds a well-defined threshold, which depends on the correlation properties of the beam (Soljacic et al., 2000). This shows that modulation instabilities (MI) can be totally suppressed by properly adjusting the correlation distance of the wave front. A natural by-product of this suppression is the observation of anti-dark incoherent solitons (a bright beam on a constant background) in self-focusing environments. Periodic trains of 1-d filaments and self-ordered 2-d lattices of light spots due to incoherent modulation instabilities were observed by carefully increasing the nonlinearity (Kip et al., 2000). Spontaneous clustering of solitons in partially coherent wave fronts initiated by random noise was also demonstrated experimentally and numerically (Chen et al., 2002). It is, in fact, an

outcome of the interplay between random noise, weak correlation, and high nonlinearity. Together, this process leads to incoherent MI, formation of 2-d solitary filaments, and eventually to clustering of 2-d solitons or in other words, aggregates of fine-scale structures. This clustering phenomenon has no counterpart with solitons in coherent systems. The rapid progress in this new area of incoherent solitons brings about many interesting fundamental ideas and possible applications. We have concentrated here on the basic features, but new ideas arise very quickly in this new, dynamic area of soliton science.

INERTIAL MANIFOLDS

In studying the dynamics of nonlinear systems, it is sometimes observed that all trajectories rapidly converge to a subspace of the phase space, leading to a simplification of the analysis through dimensional reduction. Such subspaces are called inertial manifolds (IMs) and the underlying dynamics are called inertial. In phase spaces of infinite dimension, the question is whether a finite-dimensional dynamical system can reproduce the dynamics of an infinite-dimensional one. In finite-dimensional systems, one tries to find a system of smaller dimension.

Related concepts have been introduced in sciences. In meteorology, for example, the slow manifold introduced and studied by Lorenz and others, is expected to reproduce the slow dynamics, taking into account interaction with the rapidly changing regions of the phase space. From a somewhat different perspective, the Reynolds equations in turbulence and some large eddies simulation models are finite-dimensional systems that attempt to reproduce the dynamics of the large eddies of the fluid, taking into account the action of the small eddies.

Definition

Denote by H the phase space, a Hilbert space of finite or infinite dimension, and consider on H a semigroup of operators $\{S(t)\}_{t \geq 0}$ generating the dynamical system: $u_0 \mapsto S(t)u_0 = u(t)$.

If it exists, an inertial manifold for this system is a smooth finite-dimensional manifold $\mathcal{M}$ in H that enjoys the following properties:

- $S(t)\mathcal{M} \subset \mathcal{M}$, $\forall t > 0$ (positive invariance);
- all orbits converge to $\mathcal{M}$, as $t \rightarrow \infty$, at an exponential rate;
- the rate of convergence is uniform for all orbits starting in a bounded set of initial data.

If a global attractor $\mathcal{A}$ exists, then necessarily $\mathcal{A}$ is included in $\mathcal{M}$ as well as any stationary solution, periodic orbit, etc. Comparing $\mathcal{A}$ to $\mathcal{M}$ when they both exist, we see that $S(t)\mathcal{A} = \mathcal{A}$, instead of (i), and we know that orbits may converge to $\mathcal{A}$ at arbitrarily slow rates, in contrast with (ii). Finally, attractors are believed to be sometimes fractal sets, whereas smoothness is required for $\mathcal{M}$.

When an inertial manifold exists, the restriction of the semigroup to $\mathcal{M}$ is a group—due to (i)—whose dynamics are the same as that of the initial systems.

In particular, their attractor is the same if $\{S(t)\}_{t \geq 0}$ has an attractor, and this reduced dynamical system is called an inertial system. When the dynamical system is defined by a differential equation, as in Equation (1), its restriction to $\mathcal{M}$ is a finite-differential system, also called an inertial system.

Examples

Inertial manifolds have been studied for dynamical systems in infinite dimensions corresponding to dissipative parabolic evolution equations, written in functional form as

$$\frac{du(t)}{dt} = F(u(t)), \quad u(0) = u_0. \quad (1)$$

Here $u(t) = S(t)u_0$, where u_0 and $u(t)$ belong to H .

The space H is decomposed as the sum of a finite-dimensional space $Y = P_y H$ and of its complement $Z = P_z H$, $u = y + z$. In all examples studied, the inertial manifold is then searched for as a graph:

$$z = \Phi(y), \quad y \in Y. \quad (2)$$

Usually, Y and Z are spectral spaces for the underlying linear dissipative operator A , Y representing hence the low-frequency component of the flow and z its high-frequency component.

The existence of inertial manifolds has been proven for the Kuramoto–Sivashinsky equation, the Ginzburg–Landau equation, reaction-diffusion equations in one and two spatial dimensions, and the Navier–Stokes equations with added (hyper-)viscosity.

The initial hope (Foias et al., 1988) was to find an IM for the Navier–Stokes equation at least in space two, justifying the name coined by Foias, since the role of the inertial terms over the viscous terms would be dominant on this manifold. However, the existence of an inertial manifold for the Navier–Stokes equations has not yet been proven nor disproven.

Several proofs of existence have been derived beyond those of Foias et al. (1988); the key hypothesis and limitation in all the proofs is the so-called spectral gap condition, involving a sufficiently large gap in the spectrum of the dissipative operator A . It is believed (but not proved) that this difficulty could be overcome with IMs that are less smooth and are not graphs. Alternatively, this difficulty has been overcome by removing the condition that $\mathcal{M}$ be a manifold. The corresponding concept was introduced in Eden et al. (1994) where it was called an inertial set or an exponential attractor.

The existence of inertial sets was proven in Eden et al. (1994) for numerous dynamical systems generated by evolutionary dissipative equations, in fact, for all systems for which the existence of a compact finite-dimensional attractor has been established (Hale, 1988; Sell & You, 2002; Temam, 1997).

Despite these limitations, inertial manifolds are a natural concept, giving a precise form to the idea that infinite-dimensional dynamical systems produce a finite-dimensional dynamics. Remember that a less explicit form of this idea is the property of the attractor to be finite-dimensional.

When IMs do not exist or are not easy to construct, approximate inertial manifolds (AIMs) are sometimes used, which are finite-dimensional smooth manifolds that attract the orbits in a small neighborhood. Extensive applications of AIMs in numerical analysis have been developed (Temam, 1997; Sell & You, 2002).

INFORMATION DIMENSION

See **Dimensions**

INFORMATION THEORY

Although the word *information* is commonly used and its engineering applications influence our lives, the quantitative meaning is often unclear. Among several measures of information, the most common is called Shannon information (denoted as I_S with units of the bit), which was introduced by Claude Shannon in 1948.

As an example, suppose your friend (whose wife has been pregnant for nearly nine months) telephones with the information: It's a girl. Since the prior probability (P) of a girl being born is $\frac{1}{2}$, the Shannon information is computed as

$$I_S = \log_b \left(\frac{1}{P} \right) = \log_2 \left(\frac{1}{1/2} \right) = 1 \text{ bit}, \quad (1)$$

with the logarithmic base $b = 2$. In other words, one bit of Shannon information is gained in a message that resolves one of two equally probable events.

Strings of such events (e.g., 100110100011100) are the language of computers, and their Shannon information can be computed by thinking of a string as a set of N switches, each of which can be on (1) or off (0). Since there are 2^N possible sequences of N switches, the probability of any particular sequence is 2^{-N} , leading to a Shannon information of N bits, which is conveniently equal to the number of switches.

Shannon's information takes the particular form, Equation (1), under the assumption that the received message (an observed switch sequence) is completely reliable. A more general Shannon measure allows for generally unreliable messages; thus

$$\begin{aligned} &(\text{source event } B_1 \text{ or } B_2 \text{ or } \dots B_N) \\ &\rightarrow \text{observed message } A. \end{aligned} \quad (2)$$

Here a particular source event $B_n \equiv B$ occurs, and the observer receives a message A , providing evidence of what was actually intended. The arrow implies transmission through a real, imperfect communication channel, in which transmission errors may occur. For example, the actual source event B might be the switch sequence given above that is transmitted to an observer. Because of transmission errors, the received message might be $A = 010110100011100$.

As when a detective observes a fingerprint, the message A implies that an event B has occurred, where each B_n is a different possible switch sequence. Shannon information was designed to answer the question: How much evidence does the observed (garbled) message A constitute for the hypothesis that the event B actually occurred?

Intuitively, the evidence provided by A will be strong if the probability of B having occurred is now greater than before receiving A . That is, if the probability $P(B|A)$ (of B in the presence of A) much exceeds $P(B)$ (the probability of B in the absence of A). This suggests that the ratio $P(B|A)/P(B)$ measures the weight of the evidence. Strong evidence would give a large ratio, weak evidence a small ratio. Because any monotonic function of this ratio works as well, taking the logarithm defines the Shannon information

$$I_S(A, B) \equiv I_S \equiv \log_b \frac{P(B|A)}{P(B)}. \quad (3)$$

Although the choice of a logarithmic base b is at the user's discretion, probabilities in computer codes are often powers of 2 for which $b = 2$ is the most convenient choice. Then I_S is assigned the unit of a *bit*. For a fixed channel probability ($P(B|A)$), Equation (3) discloses that the information increases as $P(B)$ becomes smaller. (In editing a newspaper, for example, an article entitled "Dog Bites Man" is not unusual enough to merit publication, but "Man Bites Dog" most definitely is.)

There is a problem with this definition of information—the observer, by hypothesis, does not know which event B_n has occurred. Therefore, he or she cannot know which information quantity, $I_S(A, B_1)$ or ... or $I_S(A, B_N)$ to compute. Furthermore, the message A may be one of a set of possibilities A_m , $m = 1, \dots, M$. All such possibilities can be taken into account by forming the grand average

$$\begin{aligned} & \left\langle \log_b \frac{P(B|A)}{P(B)} \right\rangle \\ & \equiv \sum_{m=1}^M \sum_{n=1}^N P(A_m, B_n) \log_b \frac{P(B_n|A_m)}{P(B_n)} \\ & \equiv I(A, B). \end{aligned} \quad (4)$$

Called Shannon's "mutual information," this is the quantity commonly used to evaluate the quality of communication systems. Notice that it depends upon properties of the source (the $P(B_n)$) as well as the channel (the $P(B_n|A_m)$); thus, this is a total system perspective.

If just the quality of the channel (as specified by its fixed channel probabilities $P(B_n|A_m)$) is to be evaluated, the information $I(A, B)$ is maximized through choice of a source $P(B_n)$. The resulting information, then, only depends upon the channel probabilities and is called the channel capacity since it measures the intrinsic capacity of the channel for transmitting information.

Note that Equation (4) may be evaluated in its continuous limit; thus,

$$I(X, Y) = \int \int dx dy p(x, y) \log_b \frac{p(y|x)}{p(y)}. \quad (5)$$

Is there an information measure that is appropriate for describing growth processes? Consider a generalization of Equation (5) to

$$I_{KL}(p, r) \equiv - \int dx' p(x') \log_b \frac{p(x')}{r(x')}, \quad (6)$$

which is called the Kullback–Leibler (K–L) information. The ratio p/r is describes a "cross entropy" between the probability law $p(x')$ and the reference law $r(x')$, where the vector x' is general. In the special case $x' = (x, y)$, $r(x') = p(x)p(y)$, Equation (6) becomes the mutual information in Equation (5). Another important case of the K–L information is when $r(x') = 1$, whereupon Equation (6) takes the form

$$- \int dx' p(x') \log_b p(x') \equiv H, \quad (7)$$

which is called the entropy.

Yet another special case of K–L information is obtained when $x' \equiv x$, a single coordinate, and

the reference function $r(x)$ is made to be a slightly displaced version of the probability law, $r(x) \equiv p(x + \Delta x)$, $\Delta x \rightarrow 0$. In this limit, the K–L information is found to obey

$$\begin{aligned} & - \lim_{\Delta x \rightarrow 0} \frac{1}{\Delta x^2} \int dx p(x) \log_b \frac{p(x)}{p(x + \Delta x)} \\ & = - \frac{1}{2} \int dx \frac{p'^2(x)}{p(x)} \equiv - \frac{1}{2} I_F, \end{aligned} \quad (8)$$

where I_F is the Fisher information and the usual derivative notation $p'(x) \equiv dp(x)/dx$ is used.

A useful variant of I_F is obtained by using a probability amplitude $q(x)$, where $p(x) \equiv q^2(x)$. The right-hand integral of Equation (8) then gives directly

$$I_F = 4 \int dx q'^2(x), \quad q'(x) \equiv dq(x)/dx. \quad (9)$$

Thus, Fisher information measures the gradient content of the probability amplitude curve.

Because the smallest possible mean-square error one can achieve in forming an estimate of the parameter is the reciprocal of Fisher's information, this also describes our ability to know a parameter from its measurements. Assuming all knowledge is based upon measurement, Fisher information describes quite generally our ability to know.

Physicists Leon Brillouin and David Bohm long sought a measure of information that would explain the mysteries of physics in general, including those of quantum mechanics. In particular, the question of quantum entanglement has long perplexed physicists. Consider a pair of particles that are created simultaneously as reactants from a mother particle. Measurement of one member of the pair supplies important information (such as spin) about the other member, even without measuring the latter. (This is called the Einstein–Podolsky–Rosen–Bohm, or EPRB, paradox.) In what way could information about the unmeasured particle be transmitted into a measurement of the detected one? This seems to require the realities of the two particles to be somehow "entangled." Hence, an "active information" was sought that could supply the needed information. Of course, they tried the Shannon variety, but this did not work.

Surprisingly, a form of information exists for generating the probability laws of physics that is aptly called the physical information and defined as follows. Let I be the Fisher information that is acquired in an actual measurement. Depending upon the measurement scenario, there may or may not be another, unmeasured particle accompanying the measured particle. The physical information K is the difference $K \equiv I - J$ of two Fisher informations (for simplicity we now drop the subscript F), where

$$I \equiv \sum_n I_n, \quad I_n = 4 \int dx q_n'^2(x)$$

and

$$J \equiv I/\kappa, \quad 0 \leq \kappa \leq 1. \quad (10)$$

Notice that the information I in the measurement is actually a sum of individual Fisher terms I_n . It turns out that the additive sum also defines the maximum possible value of the Fisher information. Hence, I is called the Fisher information channel capacity (as in the Shannon case). The integral form of the second Equation (10) shows that I is also a functional of the amplitude functions $q_n(x)$. This is a scalar number whose value depends upon an integral over all values x of the functions $q_n(x)$.

By the third Equation (10), J is likewise a functional of the amplitude functions; however, its form is not fixed but dependent upon the particular measurement scenario. J must be computed in any application.

Recall that I is the information level of the particle in a measurement space. In all measurements of quantum phenomena $\kappa = 1$, so $J = I$ by the third Equation (10). Thus J represents information that arises out of entanglement with that of the measured particle. We, therefore, call J the entangled information. Mathematically, it is I as evaluated in an "entanglement space." If only the measured particle is present, entanglement space is the Fourier conjugate space to measurement space. If another, unmeasured particle is present, entanglement space is the (unused) measurement space of that particle.

In Equations (10), the form of I is a sum of squares of functions q'_n (an L^2 norm or measure). Like any squared length, such a norm is invariant to rotation, and rotations may be performed in either the space of coordinates x (which are more generally of dimension 4 or higher) or of the functions $q'_n(x)$. Because J is linear in I , it also obeys such invariance, and likewise for their difference K . Such invariance suggests a state of stationarity

$$K \equiv I - J = \text{extrem.} \quad (11)$$

Equation (10), supplemented by Equations (11), is called the principle of extreme physical information or EPI (Frieden, 1998). Its solutions $q_n(x)$ obey corresponding Euler-Lagrange equations

$$\frac{d}{dx} \left(\frac{\partial k}{\partial q'_n} \right) = \frac{\partial k}{\partial q_n}, \quad k \equiv k(x),$$

$$K \equiv \int dx \, k(x). \quad (12)$$

These are wave equations whose solutions $q_n(x)$ are the amplitude functions of science. An example is the Schrodinger wave equation. Other examples are provided by growth phenomena, ranging from energy growth to crystal growth to cancer growth, with the preceding formulation leading to exponential, power

law, or logarithmic growth depending on the boundary conditions and integration constants that are assumed (Gatenby & Frieden, 2002).

In summary, Shannon information and cross entropy are valuable forms of information in communication theory, and two important outgrowths of these definitions are Fisher information and physical information. Fisher information permits one to estimate the expected error in the estimate of a parameter. Physical information permits one to derive physical laws via the EPI principle.

INHIBITION

In what is certainly one of the best-known experiments on learning, Ivan Pavlov sounded a bell and shortly after presented food to a hungry dog. After several pairings of the bell and the food, the bell came to elicit salivation, a response that it had not elicited previously. We say that the bell became an excitatory conditioned stimulus. *Excitatory* means that it acquired the ability to excite, arouse, or elicit a new behavior. But Pavlov did not limit his work to excitatory conditioning; he performed and described (Pavlov, 1927) a variety of procedures that would endow the conditioned stimulus with exactly the opposite properties. Such conditioned stimuli acquire the ability to oppose conditioned excitation and are said to be inhibitory.

The term originates from the Latin word *inhibere* and means to restrain. *Inhibere* consists of *in* "in" and *habere* "to hold." The word *inhibition* is widely used in many disciplines, such as medicine, biochemistry, physiology, neuroscience, and psychology, and its general meaning is the arrest or restraint of a process, partial or complete. In psychoanalytic theory, it describes a conscious or unconscious restraining of an impulse or desire. In neurophysiology, to which we will return shortly in more detail, it is the process opposite to

Figure 1. Excitatory and inhibitory currents have competitive effects on a single nerve cell. (a) An excitatory input in the base of a dendrite causes inward current which produces a large synaptic potential that brings the membrane potential close to its threshold. (b) An inhibitory input causes synaptic potential thus generated changes the membrane potential further below its threshold. (c) The shunting action of inhibition. When the cell receives both excitatory and inhibitory synaptic currents, the channels opened by the inhibitory pathway shunt the excitatory current, thereby reducing the excitatory synaptic potential. From Kandel et al. (2000).

excitation, or as Charles Sherrington (1933) wrote “. . . to refrain from an act is no less an act than to commit one, because inhibition is co-equally with excitation a nervous activity.” By “nervous activity” he meant “the activity of the nervous system.”

In fact, the function of all living systems and at all levels of complexity can be perceived as continuous adjustment between excitatory and inhibitory processes. The metabolic pathways are, for example, regulated by means of enzyme synthesis and inhibition. Almost all of the thousands of chemical reactions that occur in a living organism require catalysis by a specific enzyme. The character of any cell is based on its particular chemistry, which is determined by its specific enzyme composition. Genetic traits are expressed through synthesis of enzymes, which catalyze reactions that establish the phenotype. Many genetic diseases result from altered levels of enzyme production with changes in enzyme synthesis and/or inhibition. Much current drug therapy is based on the inhibition of a specific enzyme.

The nervous system continuously processes excitatory and inhibitory signals. Sherrington first pointed out that the quintessential action of the nervous system is its ability to weigh the consequences of different types of information and then decide on appropriate responses (Sherrington, 1947). He named it “the integrative action of the nervous system.” The point at which one neuron communicates with another is called a synapse, and synaptic transmission is fundamental to processes such as perception, voluntary movement, or learning. Although many synaptic connections are highly specialized, all neurons make use of two basic forms of synaptic transmission: electrical and chemical.

Each neuron in the central nervous system, whether in the spinal cord or in the brain, is continuously

bombarded by synaptic inputs from other neurons. Some are excitatory, others inhibitory. The effect of the synaptic potential—whether it is excitatory or inhibitory—is determined, not by the type of transmitter released from the presynaptic neuron, but by the type of ion channels gated by the transmitter in the postsynaptic cell. Most transmitters are recognized by types of receptors that mediate either excitatory or inhibitory potentials (for details see Kandel et al., 2000).

Synaptic contact can occur on the cell body, the dendrites, or the axon of a postsynaptic cell. The location of inhibitory inputs in relation to excitatory ones is critical for their functional effectiveness. Inhibitory short-circuit actions are more significant when they are initiated at the cell body near the initial axon segment. As a result, they can strongly curtail the influence of excitatory current on the membrane potential at the trigger zone, as illustrated in Figure 1c. In contrast, inhibitory action at a remote part of a dendrite is much less effective in shunting excitatory actions or in affecting the more distant trigger zones. Thus, in the brain, significant inhibitory input frequently occurs on the cell bodies of neurons.

Excitatory and inhibitory signals are integrated into a single response by the cell. In motor neurons and most interneurons, the decision to initiate an action potential is made by the initial segment of the axon (Figure 1, trigger zone). This region of cell membrane has a lower threshold for action potentials than the cell body or dendrites because it has a high density of voltage-dependent Na^+ channels. The neural integration involves the summation of synaptic potentials that spread passively to the trigger zone. It is critically affected by two passive membrane

Figure 2. The *sculpturing* effect of inhibition. Without inhibitory input the neuron spontaneously fires at a fixed interval. With inhibitory input that produces an inhibitory postsynaptic potential (IPSP), some action potentials are inhibited, resulting in a distinctive pattern of impulses. From Kandel et al. (2000).

properties. First, the *time constant* affects *temporal summation*, the process by which consecutive synaptic potentials at the same site are added together in the postsynaptic cell. The larger the time constant, the greater the likelihood that two consecutive inputs from an excitatory presynaptic neuron will sum to bring the cell membrane to its threshold for an action potential. Second, the *length constant* affects *spatial summation*. Neurons with a large length constant are more likely to be brought to threshold by two different inputs arising from different sites than are neurons with a short space constant.

In addition to counteracting synaptic excitation, synaptic inhibition can exert control over spontaneously active nerve cells. Many cells in the brain are spontaneously active, as are the pacemaker cells of the heart. By suppressing the spontaneous generation of action potential in these cells, synaptic inhibition can shape the pattern of firing in a cell (Figure 2).

Many mathematical models have been introduced to describe the function of the nervous system. Their complexity ranges from that of individual nerve cells to assemblies of neurons. Hodgkin & Huxley (1952) constructed a model, known as the Hodgkin–Huxley model, to explain the electrical excitability of nerve axons in terms of discrete Na^+ and K^+ currents. The Hodgkin–Huxley model is probably the best-known and the most elegant model of a biological system, exemplifying a balance between experiment and theory that has rarely been matched. To explain how trains of impulses occur in the Hodgkin–Huxley model FitzHugh (1961) used the Hodgkin–Huxley model as one member of a large class of nonlinear systems showing excitable and oscillatory behavior. The model was further analyzed by an approximately distributed pulse transition line using analog simulations (Nagumo et al., 1962) and today is known as FitzHugh–Nagumo model.

Wilson and Cowan (1972) further increased the complexity of the system. The model they proposed

was based on the properties of populations, and the single cell activity was represented not by a single spike, but rather by the spike frequency. They based their model on two main assumptions. First, the existence of spatially localized neuronal populations, based on physiological and anatomical evidence that many cells in a small volumes of cortical tissue have very nearly identical responses to identical stimuli. Second, all nervous processes of any complexity are dependent upon the interaction of excitatory and inhibitory cells. Wilson and Cowan were the first to treat inhibition as arising from exclusively inhibitory neurons. Wilson–Cowan oscillators are now widely used to describe higher functions, such as sensory information processing, learning, memory, or pattern recognition. Neural networks and chips are built for signal and image processing.

Much progress has been made in recent years toward a detailed understanding of the complex and nonlinear dynamics that underlie the Hodgkin–Huxley, FitzHugh–Nagumo, and Wilson–Cowan models. In addition, a large number of new models of synchronous oscillations have been introduced, attempting to describe features observed in the electrical activity of the brain as measured by EEG or MEG. They range from those involving details of receptors and inter-inhibitory interactions, to models depending on various nonlinear principles (see, for example, Haken, 2002).

INSTABILITY

See **Stability**

INSTANTONS

A remarkable feature of the Yang–Mills action is that there are finite-action topological soliton solutions to the classical field equations. These solitons are known as instantons or, in early papers, as pseudoparticles. The Yang–Mills action is important in particle physics; in particular, it describes the behavior of gluons, the particles that carry the strong nuclear force. Before instanton solutions were discovered in 1975 by Belavin et al. (1975), the Yang–Mills theory of the strong force appeared to have a symmetry not found in nature. This was known as the axial U(1) problem and was solved by 't Hooft who realized that one effect of the instanton solutions was to break this unwanted symmetry. This was the first example of an extended classical solution having a physical consequence in a field theory of particle physics.

In four Euclidean dimensions, the pure SU(2) Yang–Mills action is

$$S[A] = -\frac{1}{2} \int d^4x \text{trace } F_{\mu\nu} F_{\mu\nu}, \quad (1)$$

where μ and ν are space indices running from 1 to 4 and repeated indices are summed. $F_{\mu\nu}$ is a field strength tensor, a skew Hermitian 2×2 matrix field in four-dimensional space, related to a gauge potential A_μ by

$$F_{\mu\nu} = \frac{\partial}{\partial x_\mu} A_\nu - \frac{\partial}{\partial x_\nu} A_\mu + [A_\mu, A_\nu]. \quad (2)$$

The action is invariant under local gauge transformations

$$A_\mu \rightarrow A'_\mu = g A_\mu g^{-1} - \frac{\partial g}{\partial x_\mu} g^{-1}, \quad (3)$$

where g is a special unitary matrix function in four dimensions. Under this transformation $F_{\mu\nu} \rightarrow F'_{\mu\nu} = g F_{\mu\nu} g^{-1}$. One key consequence of this is that $F_{\mu\nu}$ not only vanishes when $A_\mu = 0$, but also, whenever A_μ is a gauge transformation of zero. This means that the asymptotic condition required for finiteness of the action is that A_μ approaches a gauge transformation of zero:

$$A_\mu \rightarrow -\frac{\partial g}{\partial x_\mu} g^{-1} \quad (4)$$

for $r = \sqrt{x_\mu x_\mu} \rightarrow \infty$. Now, the group of special unitary 2×2 matrices is topologically a three-sphere, and so the gauge potential on the large three-sphere at infinity gives a map from that three-sphere to the three-sphere of values of g . Maps between three-sphere are classified topologically by a single integer: the winding

number. This integer, therefore, classifies finite-action field configurations; in fact, it is the only gauge-invariant information determined by the asymptotic field behavior. The topologically nontrivial stationary points of the action $S[A]$ are instantons.

Since they are stationary points of the action, instantons obey the Euler–Lagrange equation for the action:

$$\frac{\partial}{\partial x_\mu} F_{\mu\nu} = 0. \quad (5)$$

This is known as the Yang–Mills equation. It can be shown that minimal action solutions obey a first-order equation called the self-dual equation:

$$F_{\mu\nu} = \frac{1}{2} \varepsilon_{\mu\nu\lambda\sigma} F_{\lambda\sigma}, \quad (6)$$

where $\varepsilon_{\mu\nu\lambda\sigma}$ is totally skewsymmetric in its indices with $\varepsilon_{1234} = 1$. Solutions to this equation obey the second-order Yang–Mills equation. A solution with winding number one is given by

$$A_\mu = -\frac{r^2}{r^2 + R^2} \frac{\partial g}{\partial x_\mu} g^{-1}, \quad (7)$$

where R is an arbitrary scale and g has the hedgehog form

$$g = \frac{x_4}{r} \mathbf{I}_2 + \frac{i}{r} (x_1 \sigma_1 + x_2 \sigma_2 + x_3 \sigma_3), \quad (8)$$

where $\mathbf{I}_2$ is the 2×2 identity matrix and the σ_i 's are the Pauli matrices. Allowing for gauge equivalence, there is an eight-dimensional space of winding number one instantons, four of these dimensions correspond to the choice of position in space, one to the choice of scale, and three to an overall group orientation. Although these results are particular to SU(2), other groups can be studied; the main difference is in the number of overall group orientation parameters.

The self-dual equations are integrable. In fact, many of the integrable equations of mathematical physics can be derived from the self-dual equations by demanding that the solution has some translational or rotational symmetry. Because of this integrability, solutions to the self-dual equations with winding numbers greater than one may be constructed, in principle, by twistor theory and by algebraic methods (Christ et al., 1978). There is also a simple ansatz (Jackiw et al., 1977), but this does not give a general solution.

In the 1980s, the self-dual equations revolutionized the study of smooth four-dimensional manifolds: by studying the space of solutions to the self-dual equations over different manifolds, it is possible to derive invariants, known as the Donaldson invariants (Donaldson & Kronheimer, 1990). This approach has since been largely superseded by Seiberg–Witten theory.

In the path integral approach to quantum field theory, physical values are derived by certain weighted integrations over all possible field configurations. These path integrals are often intractable, and it is common to expand the integration about the stationary points of the action. This works because of the way the action appears in the integrand of the path integral. Calculations of this type are known as semi-classical calculations because they are effectively an expansion in Planck's constant, $\hbar$. This expansion must include a sum over all possible stationary points, and so, in Yang–Mills theory, it includes a sum over instanton configurations. By studying the symmetry properties of the measure in quantum chromodynamics (QCD), the Yang–Mills theory describing the strong nuclear force, it can be shown that terms in this expansion break the axial $U(1)$ symmetry. This symmetry is unbroken if the instanton terms are omitted. The symmetry breaking allows processes that violate baryon and lepton conservation; however, the amplitudes for these effects are highly suppressed. One useful approach is to consider these processes as tunneling events between different vacua, in fact, instanton calculations in quantum field theory are very similar to Wentzel–Kramers–Brillouin (WKB) calculations in quantum mechanics.

While instantons provide a qualitative explanation for a host of phenomena in quantum chromodynamics, useful quantitative results are not available within the semi-classical approach, and even qualitatively, instanton calculations are not rigorous since they relate only to the semi-classical approximation, a truncation of the full quantum theory. The modern approach to quantum chromodynamics is lattice QCD. It is possible within lattice QCD to verify the original ideas about the role of instantons in the physics of the strong force; however, there are limits to the precision with which the lattice and semi-classical approaches can be compared (Negele, 1998).

Finite action soliton solutions in other equation systems are sometimes referred to as instantons. Examples include the finite action solutions to the forced Burgers equation, which arises in the study of turbulence, and the vortex-like solutions in the abelian Higgs model, which is related to condensed matter physics. Instantons have many similarities to the lump solitons found in certain sigma models.

INTEGRABILITY

Central problems in the integrability theory for nonlinear ordinary differential equations (ODEs) or partial differential equations (PDEs) are knowing which systems can be solved analytically and developing appropriate solution techniques. Although in some contexts the term *integrability* is not well defined, let us begin by considering two physically motivated nonlinear ODE systems that can be analytically solved.

Nonlinear Pendulum

Here, the nonlinear system is

$$\ddot{x} = ax + bx^2 + cx^3, \quad a, b, c = \text{constants}. \quad (1)$$

Multiplying both sides of this equation by $\dot{x}$ and integrating yields an intermediate integral $I = \dot{x}^2/2 - ax^2/2 - bx^3/3 - cx^4/4$, which is determined by the initial conditions: $x(t_0)$ and $\dot{x}(t_0)$. In terms of I , the solution $x(t)$ can be written implicitly as

$$t - t_0 = \int_{x_0}^x \frac{dx}{\sqrt{2I + ax^2 + 2bx^3/3 + cx^4/2}}, \quad (2)$$

where $x(t_0) = x_0$. The inversion of this formula is expressed in terms of Jacobi elliptic functions (Bryd & Friedman, 1954). Note that this system has one degree of freedom, and one intermediate integral was sufficient to obtain a solution. Because it is related to an area, the intermediate integral (I) is sometimes called a quadrature, and by extension, Equation (2) is said to be obtained by the method of quadratures.

Calogero–Moser N -Body Problem

In this example, the nonlinear system is

$$\ddot{q}_n = \sum_{m=1, m \neq n}^N 2g^2(q_n - q_m)^{-3}, \quad g = \text{constant}, \quad (3)$$

generalizations of which were studied extensively in the last three decades of the 20th century. Using a Lax isospectral deformation technique, the solution matrix $\text{diag}[q_1(t), \dots, q_N(t)]$ is found to be similar to the matrix $\tilde{Q} = [\tilde{Q}_{nm}(t)]$ defined by

$$\begin{aligned} \tilde{Q}_{nm}(t) &= \delta_{nm}[q_n(0) + \dot{q}_n(0)t] \\ &\quad + i(1 - \delta_{nm})g[q_n(0) - q_m(0)]^{-1}t. \end{aligned} \quad (4)$$

Thus, the solution to the initial value (Cauchy) problem is reduced to the algebraic task of finding the N eigenvalues of the matrix $\tilde{Q}$, and the solution formula for initial data, $q_i(0)$ and $\dot{q}_i(0)$, can be constructed from linear functions, through a finite number of algebraic operations and compositions of functions (Calogero, 2001). Equations (1) and (3) are completely integrable.

In the 19th century, Evariste Galois, Niels Henrik Abel, Joseph Liouville, and Sophus Lie tried to rationalize the process of solving differential equations by quadratures, or failing that, massaging them in such a way that useful information might be extracted. Mainly based on geometry and algebra, these efforts initiated much of the mathematics—such as classifications of differential equations in term of symmetries and conservation laws—that has dominated the 20th century. Attempts by Karl Weierstrass and Henri Poincaré to create a systematic theory of integrability are based on complex function theory.

An achievement of 19th-century mathematics was the elaboration of the theory of elliptic and Abelian functions, particularly the introduction of theta functions. A solution comprising such rapidly convergent power series is quite efficient computationally; thus, a natural question for 19th-century mathematicians was this: Which differential equations admit solutions as quotients of power series that converge in large regions, independent of initial or boundary conditions? The Cauchy–Kovalevsky theorem gives local existence for such expressions. This theme traces through the work of Sophia Kovalevsky and Paul Painlevé for nonlinear ODEs and through Bernhard Riemann and Immanuel Fuchs and their successors for linear ODEs (Hermann, 1984).

There are several results about local and global solutions of differential equations that establish existence, uniqueness, smoothness, stability, approximations, and so on; yet attempts to find exact solution formulas in the 19th century were largely unsuccessful. This is because solutions to nonlinear systems may exhibit complex behaviors—such as blow-up, shocks, chaos, fractals, and bifurcation—which are obstacles to integrability.

Poincaré put an end to the search for new integrable equations by showing that among all dynamical systems integrable ones are exceptional. Indeed, a small structural perturbation of an integrable system often destroys integrability.

Although Poincaré’s results dampened interest in the search for new integrable equations during the first half of the 20th century, the situation changed dramatically with the discovery of the inverse scattering transform as a method of solving the initial value (Cauchy) problem for the Korteweg–de Vries (KdV) equation (Gardner et al., 1967). Rapidly extended to several other nonlinear systems of scientific interest (nonlinear Schrödinger equation, sine-Gordon equation, Toda lattice, and so on), this discovery also led to the emergence of “soliton factories” during the 1980s (Zakharov, 1991).

More generally, integrability theory aims to find global information on solutions and, if possible, to solve differential equations analytically. Integrability itself is an intrinsic characteristic of differential equations, imposing constraints on the way solutions evolve in phase space and suggesting the following working definition.

Definition A differential equation is completely integrable if all solutions to well-posed initial or boundary value problems can be presented beginning with elementary functions, using finitely many algebraic operations and compositions of functions, and evaluating limits.

Algebraic operations include inverting or diagonalizing matrices; compositions of functions include inverses; and the limits can be integrals, infinite series, or asymptotes. Thus, this definition holds for cases in which solutions can be constructed explicitly. It also generalizes the notion of integrability by quadratures (Liouville integrability) that only requires computation of intermediate integrals in addition to algebraic operations and compositions of functions.

For ODEs, the Liouville–Arnol’d theorem on finite-dimensional Hamiltonian systems gives sufficient conditions, called the Liouville conditions, for guaranteeing the integrability by quadratures (Arnol’d, 1989). For a Hamiltonian system of N degrees of freedom, these conditions are:

- the existence of N integrals of motion $\{F_1, F_2, \dots, F_N\}$,
- that are functionally independent on the level surface $\{F_i = a_i\}$ containing the initial data, and
- that commute with each other under the associated Poisson bracket.

If the level surface $\{F_i = a_i\}$ is compact and connected, then the Liouville–Arnol’d theorem says that the underlying Hamiltonian system can be expressed as

$$\dot{I}_i = 0, \quad \dot{\phi}_i = \omega_i(I_1, \dots, I_N), \quad (5)$$

in the action-angle coordinate system (I_i, φ_i) of a neighborhood of the level surface. Thus, the motion is conditionally periodic along an N -dimensional torus with the frequencies ω_i , and the solution to the Cauchy problem can be completely determined by the method of quadratures. The Euler top, the Lagrange top, Kowalewski's top, the Stäckel systems, and geodesic flows on a surface are Liouville-integrable systems (Perelomov, 1990).

For PDEs, there also exist some results on integrability properties from a Hamiltonian perspective, including the bi-Hamiltonian theory (Magri, 1978) from which infinitely many symmetries and conservation laws for PDEs can be deduced. Motivated by the Liouville–Arnol'd theorem, a notion of integrability for PDEs is the existence of infinitely many conservation laws. The KdV equation is integrable in this sense, and it can also be put into a Hamiltonian form in action-angle coordinates like integrable ODEs (Zakharov & Faddeev, 1971).

The existence of infinitely many conservation laws can lead to infinitely many finite-dimensional solution varieties that can be determined analytically (Fuchssteiner, 1992), but it is not clear whether these subvarieties generate the whole infinite-dimensional solution variety. Indeed, the infinitely many degrees of freedom of PDEs introduce large diversity, obscuring their solvability and integrability properties.

The notion of partial integrability arises when systems of differential equations (both ODEs and PDEs) possess more degrees of freedom than conservation laws (Conte & Boccara, 1990). Symmetry constraints developed in soliton theory (Ma & Zhou, 2001) suggest a way to show partial integrability for PDEs through relating PDEs to integrable ODEs. The method was motivated by Moser's work on Hill's equation (Moser, 1980) and nonlinearization of Lax pairs (Cao, 1990). The results generalize the theory of finite-dimensional integrable stationary equations, suggesting the possibility of establishing a Liouville–Arnol'd theorem for infinite-dimensional Hamiltonian systems.

Since the 1970s, several criteria have arisen for testing the integrability of nonlinear PDEs, and corresponding theories include infinitely many symmetries, infinitely many conservation laws, Lax structure, bi-Hamiltonian structure, the Bäcklund transform, Hirota's bilinear form, the inverse scattering transform, and the Painlevé property (Degasperis, 1998; Gu, 1995).

An ODE or a PDE is said to possess the Painlevé property, respectively, if the movable singularities of solutions of the ODE are only poles (Ablowitz & Clarkson, 1991) or if solutions of the PDE are "single-valued" in the neighborhood of noncharacteristic, movable singularity manifolds (Weiss et al., 1983), suggesting that the Painlevé property is an indication of complete integrability (Conte, 1999). One advantage

of the Painlevé property is that it can be a tool for computing Lax pairs and conservation laws. Lax pairs, as we have seen in Equation (3), provide linear objects for solving Cauchy problems of nonlinear equations. A thorough understanding of the relationship between Painlevé singularities and integrability may suggest alternatives to the KAM notion of near-integrability (Zakharov, 1991).

The term S-integrability implies integrability of Cauchy problems by the inverse spectral transform technique (Calogero & Degasperis, 1982) or the inverse scattering transform (Ablowitz & Clarkson, 1991; Fokas, 1997). C-integrability, on the other hand, means that a differential equation can be transformed into a linear one by an appropriate change of variables. Examples of C-integrable equations are the Burgers equation and the Calogero–Degasperis–Ibragimov–Shabat equation:

$$u_t = u_{xx} - 2uu_x, \quad (\text{B})$$

$$u_t = u_{xxx} + 3u^2u_{xx} + 9uu_x^2 + 3u^4u_x. \quad (\text{CDIS})$$

These two equations are, respectively, cast into the heat equation ($v_t = v_{xx}$) and the linear KdV equation ($v_t = v_{xxx}$) under appropriate dependent variable transformations. Calogero and colleagues have made a systematic study of the construction and classification of C-integrable equations, both in $1 + 1$ dimensions and $N + 1$ dimensions (Zakharov, 1991). Although the property of C-integrability often leads to an infinity of conservation laws, the Burgers equation has only one local conservation law of differential polynomial type.

INTEGRABLE CELLULAR AUTOMATA

Integrable cellular automata (CAs) are discrete dynamical systems that possess attributes of integrability including conserved quantities, symmetries, and localized solutions. They show how to discretize a given integrable system of differential equations, maintaining the integrability property, suggesting that integrability of discrete systems and their coherent structures are inherently connected with the iterated string processing performed by automata.

The propagating solutions (or coherent objects) on certain cellular automata have been found to exhibit nondestructive collisions similar to those observed for soliton systems like the Korteweg–de Vries equation. In such cases, pulse-like disturbances propagating along a uniform nonlinear medium are represented by strings of symbols (zero-one patterns), passing through a one-way structure—the pipeline of identical automata M . The analysis of these moving objects reduces to investigating the repeated automaton action over strings, also called an iterated automaton map (IAM); $M(a^t) = a^{t+1}$, $t = 0, 1, \dots$

All known models capable of supporting such discrete localized structures are described by automata (Siwak, 2001, 2002), and a method (called ultra-discretization) leads to discrete systems in which so-

lutions of some familiar soliton equations are preserved as soliton-like patterns (Tokhihiro et al., 1999). Thus, an IAM is a fundamental discrete mechanism that supports localized soliton-like periodic structures. This is why a new term *iterons* (Siwak, 2001, 2002) has been proposed for these objects. Note also that fractals owe their existence to the iterating process of some maps.

There are two classes of iterons. The first consists of particles well known in cellular automata models (Delorme & Mazoyer, 1999) where the parallel processing of strings occurs. The second class is not widely known and consists of so-called filtrons. The filtrons are emergent coherent objects occurring in serial processing of strings (Siwak, 2001).

In parallel processing of a string a^t at a given time t all symbols a_i^{t+1} of the next string a^{t+1} are updated simultaneously, for example, by the function $a_i^{t+1} = f(a_{i-r}^t, \dots, a_i^t, \dots, a_{i+r}^t)$. When the same function f is used for all positions i , one has a 1-dimensional CA, with f being called its local function or rule. The arguments of f are determined by the so-called neighborhood window $N_i = (-r, \dots, +r)$; here N_i designates r neighbors on both sides of position i .

The listing of consecutive strings a^t for $t = 0, 1, \dots$ one under another forms what is called a space-time (ST) diagram. This diagram visualizes the evolution of a given string a^0 —the dynamics of a CA system in phase space for initial global state a^0 . Occasionally, some moving and periodic patterns of symbols or segments of a string are seen on ST diagrams of CA processing. These are just particles or signals of CAs (Delorme & Mazoyer, 1999).

The serial processing of strings is performed by a computational model called a finite (state) automaton. The Mealy type automaton is described by $M = (S, \Sigma, \Omega, \delta, \beta, s_0)$, where S , Σ , and Ω are nonempty finite sets of—respectively—states, inputs, and outputs; $\delta: S \times \Sigma \rightarrow S$ is called the next state function of M ; $\beta: S \times \Sigma \rightarrow \Omega$ is called the output function of M , and s_0 is the initial (extinction) state of the automaton. The automaton converts sequences of symbols, preserving their length. Any input string is read sequentially from left to right, one symbol at each instant of time (pulse of clock). For all $\tau = 1, 2, \dots$ the automaton:

- (i) reads input symbol $\sigma(\tau)$,
- (ii) changes its current state $s(\tau)$ onto the next one according to $\delta(s(\tau), \sigma(\tau)) = s(\tau + 1)$, and
- (iii) generates the output $\beta(s(\tau), \sigma(\tau)) = \omega(\tau)$ of the resulting string.

Thus the complete one step conversion at $a^t \rightarrow a^{t+1}$ requires a series of clock pulses τ . To consider IAMs, one has to assume the unified input-output alphabet $A = \Sigma = \Omega = 0, 1, \dots, m$. Then the automaton's operation can be described by a

Figure 1. Nondestructive collisions of filtrons ($q = 2$). (a) PST model. (b) Automaton M_1 .

sequence of operations $f_s: A \rightarrow A$, each f_s such that $f_s(a) = \beta(s, a)$.

Coherent objects of serial string processing were not known for a long time. The first model that established a bridge between discrete systems of string processing and soliton-like phenomena was the filter CA (Park et al., 1986). The PST (Park, Steiglitz, & Thurston) model was defined for $A = \{0, 1\}$ by a special space-time window (FCA window) and a nonlinear updating Boolean function $f_{\text{PST}}: A^{2r+1} \rightarrow A$. It operates by moving the window to the right along a given string a' . At each position the function f_{PST} computes consecutive elements

$$a_i^{t+1} = f_{\text{PST}}(a_i^t, a_{i+1}^t, \dots, a_{i+r}^t, a_{i-r}^{t+1}, a_{i-r+1}^{t+1}, \dots, a_{i-1}^{t+1})$$

of the resulting string a^{t+1} in such a way that $a_i^{t+1} = 1$ if and only if the sum of all window elements (which are arguments of f_{PST}) is even but not zero. It is assumed that the conversion $a^t \rightarrow a^{t+1}$ starts somewhere at left with the zero content of window (zero boundary conditions).

The PST model is an automaton and is classified as a digital parity infinite impulse response (IIR) filter. The dynamics of the PST model reveal discrete moving coherent objects capable of colliding in a nondestructive way. An example of such objects is shown in Figure 1(a).

Formal analysis of filter CAs has been given by Goldberg (1988). Goldberg has also given its first automaton-like description by means of a rapid updating rule.

Various generalizations of this model soon appeared. New updating functions were introduced, and the FCA window was modified (Jiang, 1992). A model with an infinite FCA window was given by Takahashi and Satsuma and called a soliton CA. Then, the working alphabet A was enlarged beyond binary (Fokas et al., 1990), and algebraic group operations were considered in computations of updating function.

Another approach was based on deriving the filter-CA-like description from the equations of motion of some systems and from so-called spectral problems (Bruschi et al., 1992).

It was observed that most of the models based on the FCA window perform very special cyclic processing. This led Siwak (2002) to a class of filter automata (FAs). FAs are described by three notions that are useful in physical interpretation of the IAM as a medium, namely:

- the activating function $\iota: A \rightarrow \{\text{false}, \text{true}\}$ such that $(\iota a) = \text{true} \Leftrightarrow \delta(s_0, a) \neq s_0$;
- the cyclic sequence $(h_j, f_1, \dots, f_k)$ of mappings f_s (the medium is excited); and
- the extinction conditions (the automaton returns to its extinction state s_0).

Note that the automaton equivalent of PST processing is activated by $a = 1$ (nonzero symbol). Its cyclic sequence of operations f_s is of the form $(N, A, \dots, A) = NA^r$ where N denotes negate operation, and A is identity id (or accept). The extinction condition is based on a coincidence of some string's current segment $w \in \{a0^r\}$ with the cycle of activity.

The example of IAM dynamics of some cyclic automaton M_1 for $A = \{0, 1, 2, 3\}$ is shown in Figure 1(b). When the automaton M_1 is extinguished, it rewrites input zeroes; $h_0(0) = 0$, but activated by a symbol $j \neq 0$, it performs the cycles of operations $(h_0, f_1, f_2, f_3), (h_j, f_1, f_2, f_3), \dots$ where

$$h_0 = \begin{pmatrix} 0 & 1 & 2 & 3 \\ 3 & 0 & 0 & 0 \end{pmatrix}, h_1 = \begin{pmatrix} 0 & 1 & 2 & 3 \\ 3 & 0 & 2 & 2 \end{pmatrix},$$

$$h_2 = \begin{pmatrix} 0 & 1 & 2 & 3 \\ 2 & 3 & 0 & 1 \end{pmatrix}, h_3 = \begin{pmatrix} 0 & 1 & 2 & 3 \\ 1 & 2 & 3 & 0 \end{pmatrix},$$

$$f_1 = f_3 = h_3 = \begin{pmatrix} 0 & 1 & 2 & 3 \\ 0 & 1 & 2 & 3 \end{pmatrix} = \text{id},$$

$$f_2 = \begin{pmatrix} 0 & 1 & 2 & 3 \\ 0 & 1 & 3 & 2 \end{pmatrix}.$$

Figure 2. Exemplary images of IAM dynamics—various phenomena of colliding filtrons.

Extinction occurs when the segment $w = 0000$ is read within a cycle.

The symbols of A are shown on ST diagram in order to expose so-called M -segments within strings. Each M -segment begins with an activating symbol, which is printed in bold. The tail zeroes of an M -segment, that is all consecutive zeros immediately preceding the extinction of M are denoted by bar. All zeroes read by the automaton in its state s_0 are shown as dots, and all remaining zeroes as digits 0. With this convention one can recognize whether any two M -segments are distant, adjacent, or overlap and actually form a complex object. Also, a shift q per row to the left is sometimes applied to ST diagrams.

The filtron x of automaton M within the IAM dynamics is defined to be periodic M -segment of the string $a^0 = \dots 0x0 \dots$.

Among the discrete models supporting coherent objects there are also the following. For most of them the appropriate equivalent automata have been identified (Siwak, 2001, 2002):

- iterated arrays of finite state automata (Atrubin, 1965);
- filter CA, soliton CA, and other generalizations of PST model based on FCA window;
- digital recursive (IIR) filters and filter automata family (Siwak, 2001);
- classical CAs and higher order CAs (Delorme & Mazoyer, 1999);
- CAs with mixed serial and parallel scenarios of their updating schedule;
- rapid-updating rule-type procedures called also fast rules;
- integrable CAs derived from so-called spectral problems (Bruschi et al., 1992), and discrete versions of some classical soliton equations;
- box-ball systems introduced by D. Takahashi;
- crystal systems and combinatorial data processing;

- techniques of accelerating the convergence of numerical algorithms;
- affine Lie algebras.

Let us illustrate the dynamics of IAM with automata $M_{\text{BBSC}}(m, n)$, which are equivalent to the model called the box-ball system with carrier (BBSC). In BBSC each position i represents a box, and each symbol $0 < a_i \leq m$ from A is interpreted as the number of balls. A single step of the evolution of a string is performed by a carrier of capacity n that runs to the right once and moves each ball exactly once. At each box, the carrier puts as many balls into the box as possible and simultaneously takes as many balls from the box as possible.

This means that if the carrier contains $0 \leq c_j \leq n$ balls at box j , then it will take $\min(a_j, n - c_j)$ balls from this box and, simultaneously, will leave $\min(c_j, m - a_j)$ balls. The finite state automaton $M_{\text{BBSC}}(m, n)$ that performs exactly the same string processing as this BBSC is such that: the set of states $S = \{0, 1, \dots, n\}$ and the alphabet of input/output symbols $A = \{0, 1, \dots, m\}$ are sets of integers; $s_0 = 0$ is the initial state of $M_{\text{BBSC}}(m, n)$; and the next states of $M_{\text{BBSC}}(m, n)$ are given by $\delta(s, \sigma) = s + \min(\bar{s}, \sigma) - \min(s, \bar{\sigma})$, while the output symbols are determined by $\omega = \beta(s, \sigma) = \sigma + \min(s, \bar{\sigma}) - \min(\bar{s}, \sigma)$. Here $\bar{s} = n - s$ and $\bar{\sigma} = m - \sigma$.

An example of colliding filtrons of the automaton $M_{\text{BBSC}}(16, 22)$ is given in Figure 2.

Further examples of IAM dynamics for some other automata are given in Figure 3 where among the multi-filtron nondestructive (solitonic) collisions the following phenomena can be especially seen: complex filtrons (a), (c), jumps of the filtron over a bundle (a), (b), trapped or bouncing filtrons and collision of such complexes (c), decaying object (or quasifiltron) and its earlier solitonic collision (d), vibrating filtrons (e), steady filtrons (a), (b), and attraction and repelling of filtrons (f). Also the fusion, annihilation of filtrons and

Figure 3. Six filitrons of the automaton $M_{BSC}(16, 22)$ collide solitonically (shift $q = 1$).

many other events are possible and can be seen in computer simulations—the realm of the behaviors of filitrons of automata is fascinating and amazingly rich.

The automaton approach and explanation of discrete coherent structures phenomena by IAMs leads to many applications, including computing by means of streams of filitrons (solitonic processing idea of Steiglitz), transmission and conversion of information via fiber optical lines, and signals and waves processing (e.g., by an interaction of electromagnetic waves with a shock wave background or another precisely shaped medium).

INTEGRABLE LATTICES

Lattices, or differential-difference equations (DDEs), are a special class of ordinary differential equations, with an infinite number of dependent variables $q_n = q_n(t)$ numbered by integer indices n ,

admitting a translational invariance with respect to the shift $n \rightarrow n + 1$. Due to this property, such equations are well suited for describing processes in translationally symmetric systems like crystals. By imposing suitable boundary conditions, such as periodic ones ($q_n(t) \equiv q_{n+N}(t)$ for all n), one can also model finite systems. In the notation above the dependent variable t plays the role of time; the range where the dependent variables q_n take values can be a multidimensional vector space or even a more general manifold. Sometimes it is convenient to think of n as the second, discrete independent variable, so that $q_n(t) = q(t, n\Delta x)$ is thought of as a sampling of a function $q(t, x)$ of two continuous variables (time t and space coordinate x) for the discrete sequence of values of $x = n\Delta x$. In such a context differential-difference systems appear as semi-discretizations of systems of partial differential equations (PDEs). For instance, the lattice model

$$\ddot{q}_n = \omega_0^2(q_{n+1} - 2q_n + q_{n-1}) - \sin(q_n), \quad (1)$$

used by Yakov Frenkel and Tatiana Kontorova in their study (1939) of the relation between dislocation and deformation of crystals, can be considered as a semi-discretization of the sine-Gordon (SG) equation $q_{tt} - q_{xx} = -\sin(q)$ (in this interpretation $\omega_0 = 1/\Delta x$). Subsequent developments revealed that the discrete model (1) is non-integrable, unlike its continuous counterpart SG. Thus, in hindsight, already this early example illustrates the difficult problem of integrable discretization: how to discretize one or several independent variables in a given integrable system, maintaining the integrability property.

Another early example of a physically important system of DDEs is the model used by Enrico Fermi, John Pasta and Stan Ulam in their 1955 study of the dynamics of energy partition in crystals:

$$\ddot{q}_n = -\omega_0^2(q_{n+1} - 2q_n + q_{n-1}) - \alpha((q_{n+1} - q_n)^2 - (q_n - q_{n-1})^2). \quad (2)$$

In this model, only nearest neighbors interact with the potential depending on their relative displacement, $U(\Delta q) = \frac{\omega_0^2}{2}(\Delta q)^2 + \frac{\alpha}{3}(\Delta q)^3$. Also this model is, strictly speaking, non-integrable. However, by an interesting historical twist, the studies by Fermi, Pasta, and Ulam played the precursor role for the theory of solitons. Presumably, due to the closeness of Equation (2) to integrable models, it demonstrated a lack of thermalization (the FPU recurrence phenomenon), and in attempts to understand this, Kruskal and Zabusky studied the KdV equation and eventually discovered its solitons (See **Fermi–Pasta–Ulam oscillator chain**).

The story of integrable lattices began with the discovery by Toda (1989) of the lattice with an exponential interaction of nearest neighbors, which

carries nowadays his name (See **Toda lattice**):

$$\ddot{q}_n = e^{q_{n+1}-q_n} - e^{q_n-q_{n-1}}. \quad (3)$$

He found a number of exact soliton-like solutions of this systems, both in the infinite and in the periodic setting. Multisoliton solutions were constructed in 1973 by Hirota with the help of his ingenious “direct” (or bilinear) method (See **Hirota’s method**). The integrability of this model in the sense of classical mechanics (existence of an infinite number of independent integrals of motion, which are in involution with respect to the standard Poisson bracket with canonically conjugate momenta $p_n = \dot{q}_n$), as well as in the sense of the solitons theory (Lax representation and applicability of the inverse scattering, or inverse spectral, transformation (IST)) was demonstrated in 1974 independently by Flaschka and by Manakov. Other important early work on this system includes the treatment of scattering in the finite nonperiodic Toda lattice by Moser (1975), finding the Bäcklund transformation by Wadati and Toda (1975), and the solution of the periodic lattice in terms of multidimensional theta-functions given independently by Date and Tanaka and by Krichever (1976). One has a rare possibility to read the first-hand presentation of the whole body of relevant results, including the authentic story of the original discovery, in Toda (1989).

Once the mechanism of integrability via IST for lattice systems was uncovered, new integrable DDEs began to be discovered in quick succession. The next one was the lattice

$$\dot{a}_n = a_n(a_{n+1} - a_{n-1}), \quad (4)$$

having plenty of applications and known today under various names (Volterra, Kac–van Moerbeke, discrete KdV, etc.). Its integrability was established independently by Manakov (1974) and by Kac and van Moerbeke (1975), while the multisoliton solutions for it and for its modification,

$$\dot{a}_n = (1 + a_n^2)(a_{n+1} - a_{n-1}), \quad (5)$$

had been found by Hirota in 1973.

An important paper by Ablowitz & Ladik (1976) contained a lattice version of the zero-curvature (Zakharov–Shabat) representation of integrable systems and integration methods based on it. This deepened understanding of the algebraic structures behind integrable lattices, and opened an opportunity to construct in a unified manner arbitrarily many examples. One of the celebrated systems introduced and studied there is an integrable spatial discretization of the nonlinear Schrödinger equation (DNLS):

$$\begin{aligned} i\dot{\psi}_n = & -(\psi_{n+1} - 2\psi_n + \psi_{n-1})/(\Delta x)^2 + v |\psi_n|^2 \\ & \times (\psi_{n+1} + \psi_{n-1}). \end{aligned} \quad (6)$$

A different but gauge equivalent discretization of NLS was found by Isergin and Korepin in 1981 (See

Faddeev & Takhtajan, 1987 and **Discrete nonlinear Schrödinger equations**).

Dozens of integrable lattices have been found since then (which, of course, has led to a certain devaluation of this sort of activity). It seems, however, that only a few of them are of really fundamental importance for theory and applications. Such a “short list” depends naturally on personal tastes, but the following systems (apart from those already mentioned) should be included in any case.

A sort of a relativistic generalization of the Toda lattice is due to Ruijsenaars (1990):

$$\begin{aligned} \ddot{q}_n = & (1 + \alpha \dot{q}_{n+1})(1 + \alpha \dot{q}_n) \frac{e^{q_{n+1}-q_n}}{1 + \alpha^2 e^{q_{n+1}-q_n}} \\ & - (1 + \alpha \dot{q}_n)(1 + \alpha \dot{q}_{n-1}) \frac{e^{q_n-q_{n-1}}}{1 + \alpha^2 e^{q_n-q_{n-1}}}. \end{aligned} \quad (7)$$

A Toda-type lattice with nearest neighbors interactions that encounter elliptic functions but depends not only on their relative displacements was discovered by Shabat & Yamilov (1990) and independently by Krichever (2000):

$$\ddot{q}_n = (\dot{q}_n^2 - 1)(V(q_n, q_{n+1}) + V(q_n, q_{n-1})), \quad (8)$$

where $V(q, q') = \zeta(q + q') + \zeta(q - q') - \zeta(2q)$ is an elliptic function in both arguments q, q' (here $\zeta(q)$ is the Weierstrass ζ -function).

A neat spatial discretization of the Landau–Lifshitz (LL) equation has been derived by Adler (2000):

$$\begin{aligned} \dot{s}_n = & \langle s_n, J s_n \rangle \left(\frac{s_n \times s_{n+1}}{1 + \langle s_n, s_{n+1} \rangle} + \frac{s_n \times s_{n-1}}{1 + \langle s_n, s_{n-1} \rangle} \right) \\ & - 2s_n \times (J s_n). \end{aligned} \quad (9)$$

Here $s_n \in S^2$, and J is a constant 3×3 matrix. In the isotropic case $J = I$ and this model reduces to a discrete Heisenberg magnetic discovered independently by Sklyanin and by Ishimori in 1982. Sklyanin found also a discretization of the LL equation different from (9); the relation between both models is discussed in Adler (2000).

In the rest of this article we briefly discuss some mathematical aspects of integrable lattices. We illustrate them mainly with the example of the Toda lattice (3), but almost all of this holds in one form or another for all integrable DDEs.

Lax Representations

The results by Flaschka and by Manakov of 1974 serve as a first application of IST in the differential-difference context. It is based upon the Lax representation of the Toda lattice (3), but almost all of this holds in one form or another for all integrable DDEs

$$\dot{L} = [L, A_{\pm}], \quad (10)$$

in terms of linear difference operators L and $A_{\pm}$ with coefficients depending on $q_n, \dot{q}_n$ and on the so-called

spectral parameter λ :

$$L = \sum b_n E_{n,n} + \lambda^{-1} \sum a_n E_{n,n+1} + \lambda \sum E_{n+1,n}, \quad (11)$$

$$A_+ = \sum b_n E_{n,n} + \lambda \sum E_{n+1,n}, \quad (12)$$

$$A_- = -\lambda^{-1} \sum a_n E_{n,n+1},$$

where the Flaschka–Manakov variables a_n, b_n are expressed through $q_n, p_n = \dot{q}_n$ as

$$a_n = e^{q_{n+1} - q_n}, \quad b_n = p_n. \quad (13)$$

Here we represent difference operators as infinite matrices, with $E_{m,n}$ being the matrix with the only nonvanishing element equal to 1 in the position (m, n) . In the case of the finite open-end lattice, the operators are $N \times N$ matrices; summation in the above formulas is performed for n from 1 to N , and it is assumed that $E_{N+1,N} = E_{N,N+1} = 0$. The N -periodic case differs in that it is assumed that $E_{N+1,N} = E_{1,N}$ and $E_{N,N+1} = E_{N,1}$. In the infinite and the finite open-end case, the spectral parameter λ can be removed by a conjugation with a diagonal matrix $\text{diag}(\lambda^n)$; it is not so in the periodic case, which makes the latter analytically much more difficult and demanding.

An alternative to the Lax representation is the discrete zero-curvature representation

$$\dot{L}_n = M_n L_n - L_n M_{n-1}, \quad (14)$$

first developed by Ablowitz and Ladik in 1975. It uses the same second-order operators (11), (12), but in terms of the spectral parameter-dependent 2×2 matrices

$$L_n = \begin{pmatrix} b_n + \lambda & a_{n-1} \\ -1 & 0 \end{pmatrix}, \quad M_n = \begin{pmatrix} -\lambda & -a_n \\ 1 & b_n \end{pmatrix}. \quad (15)$$

Such a representation is somewhat more flexible from the technical viewpoint.

Inverse scattering

The matrix L is similar to a symmetric tri-diagonal matrix, which means that the operator L is gauge equivalent to a second-order and self-adjoint matrix. The direct and inverse spectral theory of such operators is well-developed (see Teschl, 2000), and parallel, to a large extent, to the direct and inverse spectral theory of second-order differential operators. In the rapidly decaying case ($q_n \rightarrow c, \dot{q}_n \rightarrow 0$ as $n \rightarrow \pm \infty$) the standard IST scheme is illustrated by the following diagram.

The set of spectral data allowing for a solution of the inverse problem consists of the discrete eigenvalues μ_j , the normalizing coefficients γ_j of the corresponding discrete eigenfunctions, and the reflection coefficient $r(\zeta)$ of the continuous spectrum. Equation (10) yields that the evolution of the operator L , induced by the fact that $q_n(t)$ satisfy the Toda lattice equations (3), is isospectral. More precisely, the discrete eigenvalues are constants of the motion, while the evolution of other spectral data is governed by simple linear equations:

$$\mu_j = \text{const}, \quad \gamma_j(t) = \gamma_j(0) e^{(\mu_j - \mu_j^{-1})t},$$

$$r(\zeta, t) = r(\zeta, 0) e^{(\zeta - \zeta^{-1})t}.$$

Solution of the inverse spectral problem is given in terms of the Riemann–Hilbert problem or its variants, such as the Gel'fand–Levitan equation. Multisoliton solutions correspond to reflectionless potentials, for which $r(\zeta, t) \equiv 0$.

In the periodic case, the set of the spectral data is more complicated: it includes a hyperelliptic Riemann surface $\mathcal{R}$ of genus $N - 1$ determined by the eigenvalues of the periodic boundary value problem for the operator L ; further, it includes $N - 1$ points P_k on $\mathcal{R}$, which correspond to the eigenvalues of L with vanishing boundary conditions. Due to (10), the Riemann surface $\mathcal{R}$ itself is an integral of motion, and the evolution of points P_k is such that the image of the divisor $P_1 + \dots + P_{N-1}$ under the Abel map moves along a straight line in the Jacobi variety of $\mathcal{R}$. Solution of the inverse spectral problem is given in terms of multidimensional theta-functions. An important technical device in this type of problems constitute Baker–Akhiezer functions, which have essential singularities at P_k and are meromorphic elsewhere on $\mathcal{R}$; their analytic properties define them uniquely.

Hierarchies

Integrable lattices (and, more generally, integrable systems) do not appear separately, but are organized in hierarchies. To describe the Toda lattice hierarchy, note that the matrices $A_{\pm}$ in (12) may be seen as $A_{\pm} = \pm \pi_{\pm}(L)$, where $\pi_{\pm}$ stands for the nonnegative (resp. negative) part of the Laurent series with respect to the spectral parameter λ . This is a particular instance of a very general construction, known as the Adler–Kostant–Symes (AKS) method, dealing with a splitting of a Lie algebra $\mathfrak{g}$ into a direct sum of its two subspaces that are also Lie subalgebras $\mathfrak{g}_{\pm}$; in this general setting, $\pi_{\pm}: \mathfrak{g} \rightarrow \mathfrak{g}_{\pm}$ are the corresponding projections. The higher members of the Toda lattice hierarchy (enumerated by $m \in \mathbb{N}$) are characterized by Lax equations of form (10) with the same Lax matrix L as in (11) and $A_{\pm} = \pm \pi_{\pm}(L^m)$, see also Kupershmidt (1985).

“Explicit” Solution in Terms of a Factorization Problem

A further important ingredient of the AKS method is a formula for the solution of the initial value problem for such Lax equations. It is given in terms of the factorization problem in the Lie group G corresponding to the Lie algebra $\mathfrak{g}$ in terms of its Lie subgroups $G_{\pm}$ corresponding to $\mathfrak{g}_{\pm}$: if the elements $U_{\pm}(t) \in G_{\pm}$ solve the factorization problem $\exp(tL^m(0)) = U_+U_-$, then $L(t) = U_+^{-1}(t)L(0)U_+(t) = U_-(t)L(0)U_-^{-1}(t)$ is the solution of the m th member of the hierarchy. The factorization problem in G is, in general, a sort of Riemann–Hilbert problem, intimately related to the one participating in the inverse scattering transformation.

Darboux–Bäcklund Transformations and Discretization

The above-mentioned factorization problem in G also leads to an effective construction of Darboux–Bäcklund transformations, which are a further indispensable attribute of integrable systems. For the Toda lattice, a Bäcklund transformation $(q_n, p_n) \mapsto (\tilde{q}_n, \tilde{p}_n)$ with a parameter h , which serves also as an integrable discretization with the time step h , is a result of the following factorization: $I + hL = U_+U_-$, with a subsequent flipping of factors: $I + h\tilde{L} = U_-U_+$, where the factors are given by

$$U_+ = \sum e^{\tilde{q}_n - q_n} E_{n,n} + h\lambda \sum E_{n+1,n} \in G_+, \quad (16)$$

$$U_- = I + h\lambda^{-1} \sum e^{q_{n+1} - \tilde{q}_n} E_{n,n+1} \in G_-. \quad (17)$$

The formulas for the Bäcklund transformation seen from these factorizations, are

$$\begin{aligned} 1 + hp_n &= e^{\tilde{q}_n - q_n} + h^2 e^{q_n - \tilde{q}_{n-1}}, \\ 1 + h\tilde{p}_n &= e^{\tilde{q}_n - q_n} + h^2 e^{q_{n+1} - \tilde{q}_n}. \end{aligned} \quad (18)$$

This is a canonical transformation, possessing a classical generating function. This result was first obtained by Wadati and Toda in 1975, see also Suris (2003).

Hamiltonian Structure

The last immanent feature of integrable lattices (and, more generally, integrable systems) is their Hamiltonian structure. Often, they are even bi- or multi-Hamiltonian, as it is the case for the Toda lattice. In the Flaschka–Manakov variables (13) the equations of motion of the Toda lattice (3) are rewritten as

$$\dot{a}_n = a_n(b_{n+1} - b_n), \quad \dot{b}_n = a_n - a_{n-1}. \quad (19)$$

The canonical Poisson bracket for the variables q_n, p_n reads in the variables a_n, b_n as follows:

$$\{b_n, a_n\}_1 = -a_n, \quad \{a_n, b_{n+1}\}_1 = -a_n \quad (20)$$

(all other brackets of the coordinate functions vanish), and system (19) is Hamiltonian with respect to this bracket, with the Hamilton function $H_2 = \frac{1}{2} \sum b_n^2 + \sum a_n$. However, one can define also a different Poisson

bracket for the variables a_n, b_n :

$$\begin{aligned} \{b_n, a_n\}_2 &= -b_n a_n, \\ \{a_n, b_{n+1}\}_2 &= -a_n b_{n+1}, \\ \{b_n, b_{n+1}\}_2 &= -a_n, \\ \{a_n, a_{n+1}\}_2 &= -a_n a_{n+1}, \end{aligned} \quad (21)$$

with the following properties: it is compatible with the first one (i.e., their linear combinations are again Poisson brackets), and system (19) is Hamiltonian with respect to this bracket, with the Hamilton function $H_1 = \sum b_n$. So, the Toda lattice in the form (19) is a bi-Hamiltonian system. This was found by M. Adler in 1979. The bi-Hamiltonian property, introduced by Magri in 1978 on the example of KdV, has been established since then as an alternative (and highly effective and informative) definition of integrability. Actually, the Toda lattice (19) is even tri-Hamiltonian, since there exists one more local Poisson bracket for the variables a_n, b_n with similar properties, discovered in Kupershmidt (1985).

Higher Dimensions

Up to now, we have considered integrable lattices with one continuous and one discrete independent variables. This clearly allows for a further generalization. Integrable systems with two continuous and one discrete independent variables are well known and widely used as the models in the field theory. For instance, the Toda field theory deals with the system

$$(q_n)_{xy} = e^{q_{n+1} - q_n} - e^{q_n - q_{n-1}}, \quad (22)$$

introduced into soliton theory by Mikhailov (1979). Later it was realized that the equivalent equation $(\log v_n)_{xy} = v_{n+1} - 2v_n + v_{n-1}$, which is obtained by setting $v_n = \exp(q_{n+1} - q_n)$, appeared already in studies by Darboux in 1888, as the equation satisfied by the so-called Laplace invariants of the chain of Laplace transformations of a given second-order hyperbolic partial differential equation.

INTEGRAL TRANSFORMS

Integral transforms have their genesis in the 19th century work of Joseph Fourier and Oliver Heaviside, subsequently set into a general framework during the 20th century. The fundamental idea is to represent a function $f(x)$ in terms of a transform $F(p)$, using an integral transform pair,

$$\begin{aligned} F(p) &= \int K(p, x) f(x) dx, \\ f(x) &= \int L(x, p) F(p) dp. \end{aligned} \quad (1)$$

The functions $K(p, x)$ and $L(x, p)$ are *kernels*. If either of $f(x)$, $F(p)$ is discontinuous, further interpretation must be supplied at those points.

Oliver Heaviside invented his operational calculus to solve differential equations, such as those which arise in the theory of electrical transmission lines. A simple example is the diffusion problem (Whittaker, 1928),

$$\begin{aligned} \partial^2 u / \partial x^2 &= k \partial u / \partial t, \quad x \geq 0, \quad t \geq 0, \\ u(0, t) &= U_0. \end{aligned} \quad (2)$$

Heaviside treated differentiation as a symbolic operation, $p = \partial / \partial t$, to write the operational solution

$$u(x, t) = e^{-x\sqrt{kp}} \cdot U_0. \quad (3)$$

Using Euler's formula for differentiation,

$$\frac{d^n (x^p)}{dx^n} = \frac{p!}{(p-n)!} x^{p-n} \quad (4)$$

with n not restricted to the integers, Heaviside was able to extract all the information he required from such an approach. However, his methods met with general disapproval, leading to lifelong difficulties for him.

Heaviside's work was formalized, using the Laplace integral, to give the Laplace transform pair:

$$\begin{aligned} F(p) &= \int_0^\infty e^{-px} f(x) dx, \\ f(x) &= \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} e^{+px} F(p) dp. \end{aligned} \quad (5)$$

In the normal case, the transform integral converges for all p in a complex half-plane $\Re(p) > \alpha$, in which case the constant c in the inversion integral must be chosen to satisfy the restriction $c > \alpha$. Subjecting Equation (2) to the Laplace transform leads to the same formula (3) for the transform $U(x, p)$. Everything may be extracted from this using complex variable techniques; the complex variable p is just a placeholder for Heaviside's operational symbol $p = \partial / \partial t$.

The Laplace transform has simple properties with respect to differentiation and convolutions (Schiff, 1999). For the former, if $F(p)$ is the transform of $f(t)$, then the transform of $f'(t)$ is $pF(p) - f(0)$. Again, if $h(t)$ is the convolution of $f(t)$ with $g(t)$, defined as

$$h(t) = \int_0^t f(s)g(t-s)ds, \quad (6)$$

then the transform is given by simple multiplication:

$$H(p) = F(p)G(p). \quad (7)$$

An important area of application is systems of ordinary differential equations with constant coefficients, such as (Barnett & Cameron, 1992)

$$\mathbf{x}' = A\mathbf{x} + B\mathbf{u}, \quad \mathbf{y} = C\mathbf{x}. \quad (8)$$

Here $\mathbf{x}$ is a set of n internal state variables, $\mathbf{u}$ a set of r inputs, $\mathbf{y}$ a set of s outputs; A , B , and C are matrices. Taking the Laplace transform and using elementary matrix algebra, the response of the system is given by

$$\begin{aligned} \mathbf{Y}(p) &= G(p)\mathbf{U}(p), \\ G(p) &= C(pI - A)^{-1}B. \end{aligned} \quad (9)$$

The transform being a product, the solution is a matrix of convolutions. However, the essential information

about the system may be extracted directly, without recourse to inversion.

The Fourier transform represents functions as linear combinations of periodic functions, an idea pioneered by Fourier. A one-dimensional form is

$$F(\omega) = \int_{-\infty}^{\infty} f(t) e^{i\omega t} dt, \\ f(t) = \frac{1}{2\pi i} \int_{-\infty}^{\infty} F(k) e^{-i\omega t} d\omega. \tag{10}$$

The most common uses are (i) with time as the original variable—transformation from the time domain to the frequency domain and (ii) with spatial position as the original variable—transformation from configuration space to momentum space. The Fourier transform also has simple properties with respect to differentiation and convolution (the integral in (6) now extends from $-\infty$ to $+\infty$), making it useful for investigation of partial differential equations, as well as many more complex systems.

Other important transforms are the Hankel transform, which uses Bessel functions for the kernels in pair (1), alternative forms of the Fourier transform using sine or cosine functions, and many other lesser known pairs (Davies, 2002). In fact, every Sturm–Liouville problem generates integral transforms (Antimirov et al., 1993). In addition, there are transforms that involve complex integration in an essential way, such as the Hilbert transform and Cauchy integrals, which use principal values.

The Mellin transform pair

$$F(p) = \int_0^{\infty} x^{p-1} f(x) dx, \\ f(x) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} x^{-p} F(p) dp \tag{11}$$

has great utility, particularly in asymptotics (Ninham et al., 1992; Davies, 2002). For example, the Mellin transform representation of the exponential integral

$$\text{Ei}(x) = \int_x^{\infty} \frac{e^{-u}}{u} du, \tag{12}$$

is

$$\text{Ei}(x) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} \frac{(p-1)! x^{-p}}{p} dp, \quad c > 0, \tag{13} \\ = -\ln x - \gamma - \sum_{k=1}^{\infty} \frac{(-1)^k x^k}{k! k}, \tag{14}$$

where the infinite sum is obtained by the standard theory of residues.

The Fourier transform is particularly well suited to linear evolution problems. Typically, there is an initial configuration, $u(x, 0)$, which is represented as a linear

Figure 1. Solution of evolution equations using transforms.

superposition of plane waves,

$$u(x, 0) = \frac{1}{2\pi} \int_{-\infty}^{\infty} U(k, 0) e^{-ikx} dk. \tag{15}$$

The individual waves evolve according to a simple dispersion relation, $\omega = \omega(k)$, which means that the functions $\exp[-ikx + i\omega(k)t]$ satisfy the partial differential equation. As a consequence, the solution at later time is

$$u(x, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} U(k, 0) e^{-ikx + i\omega(k)t} dk. \tag{16}$$

The process can be visualized as in Figure 1. The top arrow indicates the required evolution of the initial state $u(x, 0)$ to the later state $u(x, t)$. The circuitous route has three steps: (i) map the initial state $u(x, 0)$ to some wave data $U(k, 0)$, (ii) evolve the wave data under the evolution equation to the later wave data $U(k, 0)e^{i\omega(k)t}$, and (iii) use an inverse transform to reconstruct the new state from the new wave data.

Beginning in the 1970s, it was realized that a large number of nonlinear evolution equations may be solved using an analogous process that has come to be known as the inverse scattering method (Dodd et al., 1982). It is more complicated than the linear methods, but reduces to them in the limit of small nonlinearity. Briefly, the nonlinear equation is associated with a linear one, and there is a mechanism for mapping the data of the former onto the data of the latter. The method again proceeds according to the scheme of Figure 1. However the inverse transform, which recovers the state from the “scattering data,” is not so simple, and the method derives its name from it. The first explicit use of this scheme was for the solution of the Korteweg–de Vries (KdV) equation, which is associated with a linear Schrödinger equation in which the function $u(x, t)$ plays the role of the potential. The evolution of the spectrum of the Schrödinger operator, in response to the nonlinear evolution of KdV equation, is linear; furthermore, in the limit of weak nonlinearity, the transform and its inverse reduce to the Fourier transform.

INTEGRATE AND FIRE NEURON

Classical electrophysiology using extracellular recording methods established the all-or-none nature of the nerve impulse—a stimulus has to be above a threshold θ for an action potential to be generated, and for rectangular stimuli, θ depends on stimulus duration T . A plot of $\theta-T$, a strength-duration curve is approximated by

$$\theta = \theta_{\text{th}}/[1 - \exp(-T/\tau)], \quad (1)$$

where θ_{th} is a constant called the rheobase and τ is a time constant. Lapicque (1907) produced the strength-duration curve of Equation (1) by a model in which subthreshold inputs $x(t)$ are integrated and decay with an exponential time course

$$V(t) = \int_0^t \exp(-(t-u)/\tau) du, \quad (2)$$

for $0 < V(t) < \theta$, and when $V(t)$ reaches threshold, an idealized action potential (a Dirac δ -function) is triggered and V is instantaneously reset to its resting value (say, $V = 0$). The subthreshold changes in $V(t)$ were represented as the response to an applied current of a resistance and capacitance in parallel. This separates the slow time scales of the subthreshold integrative

processes from the fast time scales of the action potential mechanisms. The values of the resistance and capacitance reflect not membrane parameters, but cell parameters, and so depend via surface area on cell size. Guided by the strength-duration curve, nerve or muscle, or different diameter nerve fibers can be excited.

Lapicque's integrate-and-fire model is also known as the leaky integrator and, in the case $\tau \rightarrow \infty$, the perfect integrator. Unlike the FitzHugh–Nagumo, Hodgkin–Huxley, and Markin–Chizmadzhev models, it considers only subthreshold, integrative processes, not the processes generating the action potential, and so is more suitable for modeling neuronal information processing than action potential transmission. Originally formulated as a phenomenological model for the conditions for the initiation of an action potential, it is still widely used as a model today, but as a model for the generation of neuronal spike trains and mass activity in neuronal networks. It has been modified to include both absolute and relative refractory periods, obtained as a limiting case for the Hodgkin–Huxley equations, and extended into multiple time constant and spatially extended models (Tuckwell, 1988).

If the input $u(t)$ is a constant c , the interspike intervals t_i are a solution of

$$\theta = \int_0^{t_i} \exp(-(t-u)/\tau) du, \quad (3)$$

and so the rate of firing is $1/t_i = 1/[-\tau \ln(1 - 1/c\tau)]$, showing an increased sensitivity to small amplitude inputs. Such a logarithmic relation between discharge rate and the magnitude of a constant input is observed in some primary sensory neurons, and is used as an explanation for the Weber–Fechner law of sensory psychophysics.

Gerstein & Mandelbrot (1964) introduced a random walk model for neuronal spike trains, in which the input to a perfect integrator model was a random sequence of small positive and negative steps. This was motivated by the observation that the interspike interval and scaled interval (sums of adjacent intervals) of some auditory neurons had the same unimodal, asymmetric shape; that is, assuming the spike train was a realization of a renewal point process, the interval density function was invariant under self-convolution or has a stable, or infinitely divisible, distribution. The subthreshold response of the integrate-and-fire model to small and brief positive or negative current pulses could represent the postsynaptic response of a neuron to synaptic inputs. Superposition of a (large) number of independent point processes generates a Poisson process: with appropriate constraints on how the amplitude of the steps decreases while the rate increases, the random walk becomes a white noise, leading to diffusion models for stochastic activity of neurons. The diffusion process models for $V(t)$ are approximations of the discontinuous, random walk models and are constructed to have the same first

and second infinitesimal moments. For the perfect integrator, the subthreshold $V(t)$ is a Wiener process; for the leaky integrator, an Ornstein-Uhlenbeck process. The interspike-interval probability density functions for these diffusion models are first passage time densities to an absorbing barrier, the threshold. These densities are obtained as solutions for forward or backward Chapman-Kolmogorov equations (see Holden, 1976; Tuckwell, 1988). These equations have been solved for different diffusion models, mostly numerically, but for some special cases solutions are available in closed form. The diffusion models have been extended to include time-varying threshold, temporal modulation of the rates of the excitatory and inhibitory inputs, and spatial separation filtering of the inputs. In the derivation of these diffusion models the synaptic inputs are assumed to be uncorrelated, producing a white noise input: correlation in the input, producing colored inputs, is more likely for central neurons and has profound effects on the output variability of the integrate-and-fire models (Feng, 2001).

The perfect and leaky integrators respond to a sinusoidal input by modulated spike trains with a periodically modulated spike density. At large modulation depths both models show rectification, and the leaky integrator also shows phase-locked responses. Both these nonlinear distortions are reduced by adding noise to the input (Stein et al., 1972), and so additive noise can increase the ability of a neuron to transmit signals about narrow-band, high frequencies. This provides a functional explanation for the association between the variability in sensory mechanoreceptors and the frequency of their adequate stimulus: the discharge of auditory neurons is almost random, and velocity sensitive primary muscle spindle afferents have a higher variability than length sensitive secondary muscle spindle afferents, leading to ideas of stochastic resonance. The phase locked and aperiodic responses of the leaky integrator to a periodic input has been characterized in terms of the Arnol'd tongue structure for the dominant modes, where there are low order ratios between the spiking and forcing rhythms (Coombes & Bressloff, 1999).

The success of the integrate-and-fire models in accounting for general properties of spike trains has allowed it, with simple modifications, to be applied to model spike trains from specific neurons, see for example, Herrmann & Gerstner (2002). The simplicity of the model also allows it to be used as an element in constructing population dynamic equations for large systems of coupled neurons, as in Sirovich et al. (2000).

INTERMITTENCY

Consider a dynamical system with x as the observed variable. As a function of time t , if $x(t)$ exhibits segments of relative constant values (laminar phase) interspersed by erratic bursts, we say the system dynamics is intermittent (see Figure 1). Pomeau and Manneville (1980) were the first to identify the three bifurcations in low-dimensional maps that are associated with commonly observed intermittencies. An additional mechanism for generating intermittency is related to the transverse instability of chaotic attractors confined to a manifold whose dimension is smaller than that of the full phase space, which is called on-off intermittency (Pikovsky, 1984; Fujisaka & Yamada, 1985; Platt et al., 1993).

Pomeau–Manneville type I intermittency stems from a saddle-node bifurcation. Near the bifurcating point ($x=0$) in one-dimensional maps, the dynamics are described by $x_{n+1} = x_n + \varepsilon + x_n^2$. For positive but small ε , a narrow channel near $x=0$ is formed between the nonlinear map function and the diagonal line $x_{n+1} = x_n$. When a trajectory enters the channel, it moves through it very slowly, giving rise to the appearance of a quiet laminar phase. After exiting the channel, the trajectory can display wild swings governed by nonlinear mechanisms, forming the bursting phase of the dynamics. As time progresses, ergodicity will bring the trajectory back to the channel

See also **Excitability; FitzHugh-Nagumo equation; Hodgkin-Huxley equations; Markin-Chizmadzhev model; Nerve impulses; Neurons**

again, and the process starts anew. The re-injected trajectory can land at different points inside the channel. As a result, the laminar phase has variable length, the mean of which is a statistical quantity of interest. It has been shown that the mean length of the laminar phase scales with the parameter ε as $\sim \varepsilon^{-1/2}$. As ε decreases through zero, a saddle-node bifurcation occurs, creating a stable fixed-point attractor at $-\sqrt{-\varepsilon}$ and an unstable fixed point at $\sqrt{-\varepsilon}$. Intermittency terminates at the bifurcation point $\varepsilon = 0$.

Pomeau–Manneville type II intermittency is related to a subcritical Hopf bifurcation; thus a two-dimensional map is needed for this phenomenon. In polar coordinates, the dynamics near the bifurcation point (assumed to be the origin) is $r_{n+1} = (1 + \varepsilon)r_n + r_n^3$, $\theta_{n+1} = \theta_n + \alpha$, where α is a constant rotation. For $\varepsilon > 0$, the origin is an unstable spiral. Viewing the r equation as a one-dimensional map, one again finds a channel for small r . When the trajectory is randomly injected into the channel, a quiet laminar period ensues, which is followed by a burst of chaotic behavior. The mean length of the laminar phase is shown to scale with ε as $\sim \varepsilon^{-1}$. At $\varepsilon = 0$ a subcritical Hopf bifurcation occurs. For $\varepsilon < 0$, intermittency is replaced by a stable fixed-point attractor at the origin that is accompanied by an unstable invariance circle centered at the origin.

Pomeau–Manneville type III intermittency is created near an inverse period-doubling bifurcation. Near the bifurcation point ($x = 0$), the equation of motion is $x_{n+1} = -(1 + \varepsilon)x_n + \alpha x_n^2 + \gamma x_n^3$. For this map, the channel dynamics is best seen by examining the second iterate of the above map that is easily obtained (after discarding higher-order terms) to be $x_{n+1} = (1 + 2\varepsilon)x_n + \beta x_n^3$, where $\beta = -2(\alpha^2 + \gamma)$. As ε decreases from positive values to negative values, intermittency is replaced by a stable fixed-point attractor and an unstable period-two orbit. The channel near $x = 0$ here is analogous to the channel near $r = 0$ in the type II intermittency. It is, thus, not surprising that the mean length of the laminar phase scales with the parameter ε as $\sim \varepsilon^{-1}$.

Consider an m -dimensional dynamical system that has an n -dimensional invariant manifold where $n < m$. (By invariant we mean that a trajectory initialized in the manifold stays there for all time.) Suppose that the dynamics on the manifold has a chaotic attractor that is also an attractor for the full phase space. Suppose also that, as a parameter varies across a threshold, a blowout bifurcation takes place (Ott & Sommerer, 1994) and the attractor becomes transversely unstable. If one monitors the distance between the trajectory and the bifurcating invariant manifold, this distance typically exhibits on-off intermittency (see Figure 1) immediately after the blowout bifurcation. During the laminar phase, in other words, the trajectory spends a great deal of time close to the invariant manifold,

Figure 1. An intermittent function.

producing a nearly zero value for the distance variable. The trajectory then departs the manifold rapidly and displays erratic bursting behavior for the distance variable until the dynamics brings it back close to the invariant manifold again, and the process repeats. During the laminar phase, the distance variable can be studied via a random walk model, and the interval between successive bursts follows a distribution akin to that of the first return time (Ding & Yang, 1995).

All four types of intermittencies have been studied in experimental systems. For example, Jeffries and Perez found Pomeau–Manneville type I intermittency in a nonlinear circuit oscillator (Jeffries & Perez, 1982). Pomeau–Manneville type II intermittency is characterized in a chemical reaction system by Herzel et al. (1991). Dubois et al. (1983) observed Pomeau–Manneville type III intermittency in Rayleigh–Bénard convection. Experimental studies of on-off intermittency are relatively recent. Hammer et al. (1994) are the first to report evidence of on-off intermittency in a nonlinear electronic circuit. On-off intermittency in a laser system was observed by Pisarchik and Pinto-Robledo in 2002.

INVARIANT MANIFOLDS AND SETS

An invariant set S of a dynamical system has the property that every trajectory (or orbit) that starts in S remains in S . Invariant sets are the basic building blocks of dynamical systems and almost every set that is dynamically interesting has some invariance property. Every trajectory is an invariant set, and so equilibria and periodic orbits are simple examples of such objects. Attractors are also examples of invariant sets.

An invariant set that is also a manifold (i.e., it looks like R^n locally) is called an invariant manifold. Invariant manifolds provide a natural description of the dynamics close to an equilibrium or periodic orbit (using linearization) and can also make it possible to work in lower dimensions than the phase space of the problem, since a smooth dynamical system restricted to an invariant manifold is itself a dynamical system. This reduction in dimension is at the heart of center manifold techniques and inertial manifold methods.

Invariance is a topological property and does not depend upon stability. This is often useful, and the sudden appearance or disappearance of attractors, as parameters are varied, can sometimes be understood as a change in stability of an invariant set that exists throughout the parameter region of interest. Indeed, many invariant sets, and particularly invariant manifolds, have persistence properties under perturbations of the dynamical system that make them useful when working with families of systems.

The basic definitions will be given for differential equations $\dot{x} = f(x)$ with $x \in R^n$ and solutions $x(t)$, and maps $v_{n+1} = g(v_n)$, $v \in R^n$. In both cases, the complications that arise if solutions do not exist for all time will be ignored.

For differential equations, a set S is a *forward invariant* set (resp. *backward invariant* set) if $x(0) \in S$ implies that $x(t) \in S$ for all $t \geq 0$ (resp. all $t \leq 0$). S is

invariant if it is both forward invariant and backward invariant.

For maps, a set S is a *forward invariant* set (resp. *backward invariant* set) if $v \in S$ implies that $g(v) \in S$ (resp. $g^{-1}(v) \in S$). S is *invariant* if it is both forward invariant and backward invariant.

In the remainder of this entry, some different sorts of invariant sets that arise in dynamics will be considered, illustrated by the Lorenz equations

$$\begin{aligned}\dot{x} &= \sigma(y - x), \quad \dot{y} = -y + rx - xz, \\ \dot{z} &= -bz + xy,\end{aligned}\tag{1}$$

where σ , r , and b are positive constants.

Trapping Regions

A set R is a trapping region if it is forward invariant and if all solutions are eventually contained in R . Trapping regions provide the first approximation to the location of any attractors in the system.

For the Lorenz equations, (1), with $\sigma = 10$ and $b = \frac{8}{3}$ Sparrow (1982) shows that the region

$$R = \{(x, y, z) \mid rx^2 + 10y^2 + 10(z - 2r)^2 \leq 5r^2\}\tag{2}$$

is a trapping region. This can be proved using the Lyapunov function $V(x, y, z) = rx^2 + 10y^2 + 10(z - 2r)^2$.

Stable and Unstable Manifolds of Stationary Points

A stationary point of the differential equation $\dot{x} = f(x)$ is a solution that is constant for all time, so it must satisfy $f(x) = 0$. The three equations obtained by setting $\dot{x} = \dot{y} = \dot{z} = 0$ in (1) can be solved to show that the origin is always a stationary point of the Lorenz equations, and provided $r > 1$, there are two other stationary points: $(\pm \sqrt{b(r-1)}, \pm \sqrt{b(r-1)}, r-1)$. Near a stationary point, the most important terms of the differential equation are the linear terms, so it is natural to ask whether the solutions of the linearized equation at the origin

$$\dot{x} = \sigma(y - x), \quad \dot{y} = -y + rx, \quad \dot{z} = -bz\tag{3}$$

obtained by ignoring the nonlinear terms in (1) reflect properties of the full equations close to the stationary point at the origin. These results are usually stated in terms of the eigenvalues of the matrix that defines the linear equation (3):

$$M = \begin{pmatrix} -\sigma & \sigma & 0 \\ r & -1 & 0 \\ 0 & 0 & -b \end{pmatrix}.\tag{4}$$

If M has no eigenvalues with zero real parts, then the manifold (vector space) spanned by the eigenvectors with eigenvalues having negative real parts contains all the stable directions and, hence, is called the stable manifold of the linear system, (3), while the manifold spanned by the eigenvectors with eigenvalues having positive real parts contains the unstable directions. The former manifold is called the stable manifold, E^s , of the origin, and the latter is the unstable manifold, E^u . If $0 < r < 1$, then all the eigenvalues of M are negative, so the stable manifold of the linear system is the whole space, and the unstable manifold is the empty set. If $r > 1$, then M has two negative eigenvalues and one positive eigenvalue, so the unstable manifold of the linear system is a line, and the stable manifold is a plane.

This provides definitions of stable and unstable manifolds for linear systems such as (3) with no eigenvalues with zero real parts. To extend the definition to nonlinear systems, we begin by noting that in the definition used for linear systems, the stable manifold of the origin contains the solutions that tend to the origin in forward time, and the unstable manifold contains those that tend to the origin in backwards time. These properties can be used to define the stable and unstable manifolds of a stationary point x^* for a nonlinear system: the stable manifold of x^* , $W^s(x^*)$ is the set of initial conditions for which the solution $x(t)$ tends to x^* as $t \rightarrow \infty$, while the unstable manifold, $W^u(x^*)$, is the set of initial conditions for which the solution $x(t)$ tends to x^* as $t \rightarrow -\infty$. The stable manifold theorem states that provided the matrix that defines the linearized equation near a stationary point has no eigenvalues with zero real parts, then $W^s(x^*)$ and $W^u(x^*)$ exist, are invariant sets, and are of the same dimension as the corresponding linear stable and unstable manifolds. Moreover, they are each tangential to the corresponding linear manifold at the stationary point itself. See Guckenheimer & Holmes (1983) for more details.

Calculating Stable and Unstable Manifolds

The stable manifold theorem suggests how approximations to the stable and unstable manifolds of a stationary point can be calculated close to a stationary point. First, it is tangential to the corresponding linear manifold, and second, it is invariant. This is enough to obtain a power series solution, and this will be illustrated using the unstable manifold of the origin of the Lorenz equations with $\sigma = 1$ and $r = 4$.

Step 1 (Linear approximation): The eigenvalues of M in equation (4) are 1, -3, and $-b$ if $\sigma = 1$ and $r = 4$. The unstable manifold is one-dimensional, and the unstable manifold of the linear approximation is the eigenvector corresponding to the positive eigenvalue, that is, $(1, 2, 0)$ or $y = 2x$, $z = 0$.

Step 2 (Canonical form): It is good practice to bring the linear part into canonical form at this stage, see Guckenheimer & Holmes (1983). For brevity this step will be omitted.

Step 3 (Power series): Since the unstable manifold is tangential to the linear approximation of Step 1 at the stationary point, it can be represented *locally* as a function of one of the variables. From the form of the linear approximation, either x or y can be used here. If the defining equations are smooth, then the stable and unstable manifolds are smooth, so choosing x as the independent variable we write

$$y = 2x + \alpha x^2 + O(x^3), \quad z = \beta x^2 + O(x^3), \quad (5)$$

where the linear terms are obtained from the linear approximation, α and β are constants to be determined, and $O(x^3)$ denotes the terms of order x^3 and higher that are small (locally) compared with the linear and quadratic terms. To identify the constants α and β , two different ways of calculating $\dot{y}$ and $\dot{z}$ are used and then compared in the next three steps.

Step 4 (Power series evolution): Differentiating (5) gives $\dot{y} \sim 2\dot{x} + 2\alpha x\dot{x}$ and $\dot{z} \sim 2\beta x\dot{x}$ (ignoring the higher order terms). Now, on the unstable manifold given by (5) $\dot{x} = -x + y \sim x + \alpha x^2$, so

$$\begin{aligned} \dot{y} &\sim 2(x + \alpha x^2) + 2\alpha x^2 \sim 2x + 4\alpha x^2, \\ \dot{z} &\sim 2\beta x^2, \end{aligned} \quad (6)$$

where higher-order terms have been ignored again.

Step 5 (Differential equation evolution): From (1) and (5) with $r = 4$ and $\sigma = 1$,

$$\begin{aligned} \dot{y} &= 4x - y - xz \sim 2x - \alpha x^2, \\ \dot{z} &= -bz + xy \sim -b\beta x^2 + 2x^2. \end{aligned} \quad (7)$$

Step 6 (Equate coefficients): To determine the two constants α and β , we now simply equate coefficients of powers of x in (6) and (7). From the $\dot{y}$ equations $4\alpha = -\alpha$, so $\alpha = 0$, and from the $\dot{z}$ equations $2\beta = -b\beta + 2$, so $\beta = 2/(2+b)$. This gives the second-order approximation to the unstable manifold:

$$y = 2x + O(x^3), \quad z = \frac{2}{2+b}x^2 + O(x^3), \quad (8)$$

which is valid close to the stationary point at the origin. Higher-order terms can be calculated by including more terms in the power series expansions.

Center Manifolds

If the matrix that defines the linearized differential equation at a stationary point has eigenvalues with zero real parts, then three invariant manifolds can be defined: a strong stable manifold corresponding to

eigenvalues with negative real parts, a strong unstable manifold corresponding to eigenvalues with positive real parts, and a center manifold that is tangential at the stationary point to the space spanned by the eigenvectors corresponding to eigenvalues with zero real parts. The motion on the strong stable and unstable manifolds is defined by the dominant linear terms, that is, towards and away from the stationary point, respectively. The motion on the center manifold depends on the nonlinear terms of the differential equation and may be stable or unstable or neutral. Center manifolds can be approximated locally using the same ideas as the approximation of the unstable manifold above, and this leads to the technique of center manifold reduction, which is central to the development of bifurcation theory. The origin of the Lorenz equations has a one-dimensional center manifold if $r = 1$ (M in (4) has an eigenvalue of zero), which signals the bifurcation creating the nontrivial pair of stationary points if $r > 1$.

Unstable Chaotic Sets

The chaotic sets created by horseshoes are not stable, but they can be important from two points of view. First, if an unstable chaotic set exists in a system then it can manifest itself in chaotic transients before a stable attractor is reached. Second, if there are parameters in the system then the chaotic set may gain stability and so the sudden appearance of strange attractors can be explained by understanding the change of stability of a chaotic invariant set. Grebogi et al. (1982) describe some of these mechanisms as *crises*. In the Lorenz equations with $b = \frac{8}{3}$ and $\sigma = 10$, a strange invariant set (an unstable chaotic set with a fractal structure) is created by a homoclinic bifurcation as r is increased through $r \approx 13.93$, but it does not become stable until $r \approx 24.06$; see Sparrow (1982); for details.

There are many other types of invariant sets and properties of these sets that could have been described here—the selection above is only the tip of an invariant iceberg.

INVERSE PROBLEMS

Scientists try to interpret the world in terms of mathematical models that depend on parameters by relating their models to the results of measurements. Thus, a model is given when a set $\mathcal{C}^0$ of parameters is mapped into a set $\mathcal{E}^0$ of experimental results. Explicit calculations of this mapping $\mathcal{M}$ are called “solving the direct problem.” Providing an exact or approximate way for going back from experimental results to parameters by $\mathcal{M}$ is called “solving the inverse problem” (Sabatier, 2000).

Because the exact limits of $\mathcal{C}^0$ and $\mathcal{E}^0$ are difficult to define, they are embedded in convenient mathematical spaces, $\mathcal{C}$ and $\mathcal{E}$, usually linear normed spaces, where it is understood that $\mathcal{C}$ is the domain of $\mathcal{M}$ and $\mathcal{M}(\mathcal{C}) \subseteq \mathcal{E}$. Because of measurement errors, there may be measurement results belonging to $\mathcal{E}$ but not to $\mathcal{M}(\mathcal{C})$, and if it is so, the inverse problem is said to be overdetermined. To appraise uncertainties on measurements, the norm of $\mathcal{E}$ must be reasonably defined, corresponding to our physical knowledge of errors.

The inverse problem is said to be “well-posed” if the norm of $\mathcal{E}$ is reasonably defined, $\mathcal{C} = \mathcal{C}^0$, $\mathcal{M}(\mathcal{C}) = \mathcal{E}$, and $\mathcal{M}$ has a two-sided inverse $\mathcal{M}^{-1}$, which is continuous for the canonical distance in $\mathcal{E}$. Then given any measurement result $e \in \mathcal{E}$, $\mathcal{M}^{-1}e$ yields parameters $x \in \mathcal{C}$ such that

$$\mathcal{M}x = e. \quad (1)$$

If a small error in the experimental data e implies that the error in the parameters x is small, the solution x is stable. Unfortunately, almost all inverse problems of physics or engineering are “ill-posed” (i.e., not well-posed).

For an ill-posed problem, a regularized solution is a continuous mapping $\overline{\mathcal{M}}$ from $\mathcal{E}$ to $\mathcal{C}^0$ such that $\mathcal{M}(\overline{\mathcal{M}}e)$ is close to $e \in \mathcal{E}$. Because experimental observations define $\mathcal{C}^0$ only approximately, one often imposes additional requirements to ease the regularizing processes, for example, that $\mathcal{C}^0$ is compact (Engl et al., 2000).

Classical examples of regularized solutions for Equation (1) are obtained by minimizing over x in one of two ways: either successively as a Euclidean distance in $\mathcal{E}$ that models the misfit and a Euclidean distance in $\mathcal{C}$ that models the non-reliability or as a combination of their squares into a cost function. Typical is the Tikhonov cost

$$C(x, x_0, \lambda) = \|x - x_0\|_{\mathcal{C}}^2 + \lambda \|\mathcal{M}x - e\|_{\mathcal{E}}^2, \lambda > 0, \quad (2)$$

where two parameters (the “first guess” x_0 and the balance parameter λ) are to be chosen. (λ may be related to an evaluation of the noise/signal ratio or to the stability, whereas “physical” information on x_0 may be suggested by previous results.)

If $\mathcal{M}$ is differentiable, the cost function (2) is also differentiable, and elementary variational calculus applies. Information from statistical analyses is more conveniently represented by quadratic cost functions similar to Equation (2), but involving noncanonical distances in $\mathcal{C}$ and $\mathcal{E}$ that are constructed from covariance matrices (having many more arbitrary parameters). The minimum x_m is unique for a given quadratic cost function and Hilbert spaces $\mathcal{C}$ and $\mathcal{E}$ if $\mathcal{M}$ is linear and continuous and satisfies the requirements of a regularized solution. This minimum can be derived either by solving linear equations or by choosing among many ones an efficient iterative algorithm.

The value $C(x_m)$ is a trade-off between requirements on $\mathcal{C}$ and $\mathcal{E}$. Either it is larger than the largest number C_M allowed for this trade-off, so that there is no admissible regularized solution of this form, or it is smaller than C_M , and all values of x such that $C(x_m) \leq C(x) \leq C_M$ are also admissible solutions of Equation (2). Hence the range of this non-uniqueness can be appraised along the principal axes of the ellipsoid $C(x) = C_M$, whose center is x_m . In this linear case, the center is given by the formula $(M^*M + \lambda I)^{-1} M^*e$, where the regularising process is clearly due to adding λ^{-1} to the eigenvalues of M^*M (the “singular values of M ”). Extensions along the axes are trivially related to the inverse of $\mathcal{M}$ singular values, damped by means of λ .

Instabilities related to the small singular values (high spatial frequencies) make this kind of regularized solution more sensitive to accidental large deviations of data (less robust) than regularized solutions obtained from cost functions involving L^1 or L^∞ norms. However, choosing the later norms usually leads one to more complicated algorithms and to (bang-bang) solutions piecewise equal to the possible upper and lower bounds. Hence, simple and efficient analyses can be adapted to almost any linear (or linearized) inverse problem, including those important for medical tomography and most medical imaging (Bertero & Boccacci, 1998).

Among many examples of nonlinear inverse problems is the case when the a priori information on a first guess x_0 is so convincing that we seek a unique approximate solution of Equation (1) in a narrow neighborhood of x_0 , allowing linearization $\mathcal{M}$. The only difference between such a linearized inverse problem and a linear one is that the conditions limiting $\mathcal{C}_0$ must involve those that ensure the relevance of our approximation.

A quite different case involves nonlinear inverse problems for which $\mathcal{M}$ is so general (with weak a

priori conditions) that we cannot escape an exhaustive exploration of $\mathcal{C}^0$ for seeking the exact or approximate solutions of (1). Random walks through $\mathcal{C}^0$ can do the job, for example, Monte-Carlo methods, simulated annealing, or genetic algorithms.

Between these extreme cases are those that correspond to important physical or engineering problems, for which studies either give an exact method of solution or allow solution of the inverse problem by numerical techniques. Defining cost functionals and minimizing them by gradient iterative or other methods (Engl et al., 2000; Ghosh Roy & Couchman, 2002) is then possible, but the occurrence of several secondary minima can also make the job difficult, raising questions about their relevance as admissible solutions.

Solving an inverse problem means that we are able to derive all the admissible regularized solutions. If the non-uniqueness is due not only to small data or parameters deviations but to the structure of $\mathcal{M}$, these equivalent solutions should be classified into identified families. This is essential either to derive ways of restoring uniqueness (for instance, by making other kinds of measurements), to use the non-uniqueness (e.g., to design stealth targets), or to modify the nature of the model. In decisive as opposed to descriptive modeling, well-posed questions seek significant pieces of information instead of trying to get an image of the parameters.

A One-dimensional Example

Inverse scattering in one spatial dimension offers some completely solved examples, the simplest one being the Schrödinger problem on the line (Chadan & Sabatier, 1989; Aktosun & Klaus 2002), which may model observations of quantum, acoustic, or electromagnetic scattering. Experimental results are the scattering coefficients $R(k)$ and $T(k)$, $k \in \mathbb{R}$, related to the parameter $V(x)$ by the following formulas, where indices $\pm$ at the same level correspond to

$$\left[-\frac{d^2}{dx^2} + V(x) \right] f^\pm(k, x) = k^2 f^\pm(k, x), \quad (3)$$

$$e^{\mp i k x} f^\pm(k, x) \rightarrow 1 \text{ as } x \rightarrow \pm\infty, \quad (4)$$

$$T(k) f^-(k, x) = f^+(-k, x) + R(k) f^+(k, x), \quad (5)$$

where $\int_{-\infty}^{+\infty} |V(x)| (1 + x^2) dx < \infty$. Equation (3) shows that $\mathbb{R}$ is the continuous part of the spectrum of $-d^2/dx^2 + V$, which has also a finite number of eigenvalues $k = i k_n$, $n = 1, 2, \dots, N$, corresponding to eigenfunctions in $L^2(\mathbb{R})$, with normalizing constants

ρ_n . The set $\{R(k), \kappa_n, \rho_n\}$, called the scattering (or spectral) data, defines the following function on $\mathbb{R}^+$:

$$S(z) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} dk R(k) e^{ikz} + \sum_{p=1}^N \rho_p e^{-\kappa_p z}. \quad (6)$$

Although knowledge of $R(k)$ and $T(k)$ is not sufficient to determine V , the spectral data is sufficient to determine everything (V , $f^\pm$, T , etc.). In fact, $\int_x^\infty V(t) dt$ is equal to $2K(x, x^+)$, where $K(x, y)$ has been derived from S by solving the linear integral equation:

$$K(x, y) + S(x + y) + \int_x^\infty dz K(x, z) S(z + y) = 0. \quad (7)$$

Only the step $K \rightarrow V$ is (weakly) instable; hence, the inverse problem ($R \rightarrow V$) is completely solved but with a structural non-uniqueness distributed into families labeled by κ_n and ρ_n .

If we let t be an evolution parameter (time) and assume that the evolution of $S(k, t)$ is described by a linear equation, the evolution of the corresponding $V(x, t)$ is generally not linear. Hence, the couple direct-inverse problem can be used to linearize special nonlinear equations. This observation provides the basis of the inverse scattering transform (IST), where the discrete eigenvalues (κ_n) correspond to solitons.

Three-dimensional Inverse Scattering

The simplest model for inverse scattering in three spatial dimensions obeys the equations:

$$(-\Delta + V) \Psi(\mathbf{k}, \mathbf{x}) = k^2 \Psi(\mathbf{k}, \mathbf{x}) \quad (8)$$

$$\Psi(\mathbf{k}, \mathbf{x}) = \exp[i\mathbf{k} \cdot \mathbf{x}] + x^{-1} \exp[ikx] F\left(\widehat{\mathbf{x}}, \widehat{\mathbf{k}}, k\right) + O(x^{-1}), \quad (9)$$

where the bold font indicates vectors (italics their length) and the hatted letters are elements of the unit sphere.

The scattering potential V is the parameter to be determined, and F the experimental observation, which in the general case depends on 5 variables, whereas V depends only on 3. Hence, the most general inverse problem is severely ill-posed. On the other hand, spherical symmetry may reduce it to a one-dimensional problem.

If V is a piecewise continuous parameter, the general case at fixed k can be treated by standard optimization techniques. However, in most target identifications (including sonar and radar), the scatterer is

not modeled by a medium function $V(\mathbf{x})$ but by a reflecting (or absorbing) surface. In some cases, approximate methods are relevant—ray theory, physical optics, Rytov approximation, distorted wave Born approximation (DWBA)—and they often yield linear relations between well-chosen parameters and data, for example, the (inversible) Abel integral, which relates the velocity of an earthquake signal as a function of depth to the measured travel time as a function of the ray parameter. If in mineral prospecting by seismic reflection surveys, geological information and rough identification of the signals suggest that the underground structure may be represented as a homogeneous medium with few reflectors, so-called migration methods may be useful. (Migration methods reposition returned signals that are time-distorted to their true location in time, for example, for dipping structures.)

Unfortunately, the exact relations between scatterers and data are highly nonlinear. Inversion of the DWBA fails in diffraction tomography as the structural complexity increases and so do optimization methods in seismic problems (nonconvexity of cost functions, secondary minima, etc.). Studies of stealth targets also involve nonlinear inverse problems, but of course they are not well documented in the open literature.

Full studies of the inverse problems of target identification are available in well-known works (for approximations, see Langenberg, 1987; Hopcraft & Smith, 1992; for mathematics, see Colton & Kress, 1992; for comprehensive studies, see topics 1.3 to 1.5 in Pike & Sabatier, 2002. For direct and inverse problems of elastic waves, see topics 1.7 and 1.8 in Pike & Sabatier, 2002.) Acoustic soundings used in clinical medicine (i.e., ultrasound scans) show graphs of travel times between source and reflectors (i.e., impedance discontinuities), giving evidence of imaging reflectors without need of solving inverse problems and so do more precisely devices transmitting back a time-reversed version of the recorded wave field (Fink & Prada, 2001).

A few techniques of medical imaging yield inverse problems that are either linearizable or nonlinear, according to a priori information and constraints. Among these, electrocardiography (Johnston, 2001), electroencephalography, and magnetoencephalography try to determine the electrical activity in the heart and the brain as functions of space and time. In brain imaging, the number of data points (~ 100) and that of unknowns ($\sim 10,000$) make the linear problem severely underdetermined, leading to arbitrary choices in the space of parameters (Bayesian approaches are commonly used) and to low resolution. From improved a priori knowledge, on the other hand, one can assume relatively few localized active groups at a given time, which are the sources of activity, but the problem becomes nonlinear (Baillet et al., 2001).

INVERSE SCATTERING METHOD OR TRANSFORM

The story begins one August day in 1834 on the Union Canal near Edinburgh. John Scott Russell observed a mass of water, displaced by the motion of a barge, race away along the channel and disintegrate into a series of waves, the likes of which he had not seen before. Following on horseback, he noted the lead wave was about 30 ft long and about a foot high. It was a wave purely of elevation above the mean level of the canal, and it traveled at about eight miles/hr without change of shape or loss of speed for a great distance. It took another 40 years before Joseph Boussinesq and Lord Rayleigh verified that such a solitary wave was indeed a solution of the shallow water equations. Twenty years later, in 1895, Diederik Korteweg and Hendrik de Vries (KdV) wrote down the now famous, universal, and ubiquitous KdV equation

$$q_t + 6qq_x + q_{xxx} = 0 \quad (1)$$

for the scaled elevation $q(x, t)$ of a right-going wave in a frame of reference moving with the shallow water

speed $\sqrt{gh_0}$ on a layer of water of depth h_0 and its solitary wave solution

$$q(x, t) = 2\eta^2 \operatorname{sech}^2 \eta(x - x_0 - 4\eta^2 t). \quad (2)$$

In the shallow water context, the elevation is

$$Ah_0 \operatorname{sech}^2 \left\{ \frac{\sqrt{3A}}{2h_0} (x - \sqrt{gh_0} (1 + A/2)t - x_0) \right\},$$

where g is the acceleration of gravity, A is the arbitrary dimensionless (small) height, and x_0 is the starting position of the wave.

The story continues almost 60 years later in Los Alamos. The question under address was totally different. Why do solids have finite rather than infinite heat conductivity? Peter Debye had suggested in 1916 that the anharmonicity (weak nonlinearity) of the interatomic forces hindered energy transport by coupling all the natural vibrations of the solid; thus, the relaxation time to thermal equilibrium would be a measure of conductivity. Enrico Fermi, John Pasta, and Stan Ulam (FPU) decided in the early 1950s to simulate numerically a model embracing this idea. The model consisted of 63 equal masses m attached by 64 springs with the force in each of them given by $k(\Delta + \alpha\Delta^2)$, a nonlinear modification of Hooke's law where Δ represents displacement from equilibrium. The initial energy was all in the lowest mode. As expected, very soon energy spread to the first few harmonics. But then a surprising thing occurred. The energy did not thermalize! Instead, after a while, it all recollected into the lowest mode. The pattern repeated. The negative outcome of the FPU experiment, one of the first scientific discoveries by computer experiment, was considered a great mystery (See **Fermi–Pasta–Ulam oscillator chain**).

Carpe Diem

The moment was seized by two young applied mathematicians, Martin Kruskal and Norman Zabusky (KZ). Because most of the energy of the FPU experiment resided in the low modes, Kruskal and Zabusky argued that they could replace the spring equations for the lateral displacements $y_n(t)$, $n = 1 \dots 63$ by a continuum approximation $y(x = nh, t) = y_n(t)$, where h was the unstretched spring length. For disturbances traveling in one direction in a frame moving with the lattice velocity $c = \sqrt{k/m}h$, the suitably scaled strain $q(x, t) = y_x/6$ obeyed the KdV equation (1). They numerically simulated solutions of (1) on a periodic domain of length L beginning with $q(x, 0) = (\pi a/6) \cos(2\pi x/L)$. They found that the solution evolved toward a sequence of solitary wave pulses each very close to (2) in shape that ran around the interval with the taller, faster ones periodically catching up with the slower ones, thereby

producing partial, and occasionally nearly perfect, recurrences. Moreover, they made one startling observation. After a pairwise collision, the two solitary waves would emerge with their former identities (amplitude, width, and speed) intact. The only evidence that the interaction was nonlinear was a phase shift. The faster (slower) pulse seemed to advance (regress) by a fixed amount. Because the solitary waves exhibited such robust, particle-like properties, Kruskal and Zabusky called them solitons (*See Solitons, a brief history*).

Such behavior indicated that the KdV equation was somehow special and that its special properties were connected with hidden symmetries and conservation laws, beyond those connected with mass, momentum, and energy. A systematic search led to the Miura–Gardner transformation, $q(x, t) = w(x, t) + \varepsilon w_x(x, t) + \varepsilon^2 w^2(x, t)$, a Riccati equation mapping solutions of a modified KdV equation $w_t + 6(w + \varepsilon^2 w^2)w_x + w_{xxx} = 0$ into solutions of (1). The single conservation law $w_t + (3w^2 + 2\varepsilon^2 w^3 + w_{xx})_x = 0$ and the corresponding conserved quantity $\int w dx$ (the integration interval is either infinite with $w(\pm\infty, t) = 0$ or finite with $w(x + L, t) = w(L, t)$) gave rise to an infinite number of conservation laws or conserved quantities for KdV, found by solving w iteratively in power of ε . Solving the Riccati equation by setting $w + 1/2\varepsilon^2 = v_x/\varepsilon v$ gives

$$v_{xx} + (q(x, t) + \lambda)v = 0, \quad (3)$$

the Schrödinger equation with energy λ and potential $-q(x, t)$. This connection of solutions of KdV with the Schrödinger operator $L(t) = -d^2/dx^2 - q(x, t)$ gave rise to the inverse scattering method. By this stage Kruskal had been joined by colleagues Gardner, Greene, and Miura (GGKM).

A Natural Question

In the late 1960s, GGKM began by asking: As the potential $-q(x, t)$, defined on $-\infty < x < \infty$ and decaying to zero as $x \rightarrow \pm\infty$, evolves according to (1), how does the spectrum (the set of eigenvalues) of (3) change? The character of the spectrum was already well known. It consists of a discrete number N of negative energy levels $\lambda_n < 0$, ($1 \leq n \leq N$), with corresponding eigenfunctions that are square integrable and a positive continuous spectrum $\lambda > 0$. Direct substitution of $q(x, t)$ from (3) into (1) gave $\lambda_t v^2 + (uQ_x - u_x Q)_x = 0$ with $Q \equiv v_t + v_{xxx} - 3(\lambda - q)v^2$. For bound state eigenvalues, the integral of the second term vanishes giving $\lambda_{nt} \int_{-\infty}^{\infty} v_n^2 dx = 0$ so that λ_n is a motion constant. It turns out that $-2\lambda_n$ is the amplitude of the n th soliton which is contained in $q(x, t)$. The fact that it is constant is the reason for the special collision property of solitons. Because $\lambda_t = 0$, $uQ_x - u_x Q = \text{constant}$, which

can easily be solved for Q to give an equation for the evolution of the eigenfunction $v(x, t)$

$$v_t = B \cdot v = -4v_{xxx} - 6qv_x + (C - 3q_x)v, \quad (4)$$

which is also equal to (remember $\lambda v = -v_{xx} - qv$)

$$v_t = B \cdot v = (q_x + C)v + (4\lambda - 2q_x)v_x. \quad (5)$$

The parameter C is a constant of integration that is used to normalize in a convenient way solutions of (3) called Jost functions. The compatibility $(v_{xx})_t = (v_t)_{xx}$ of (3) and (4) or (5) gives (1).

Peter Lax provided an elegant formalism for this compatibility. Differentiating $L(t)v = [-v_{xx} - q(x, t)v] = \lambda v$ with respect to t and using (4), one obtains $L_t = [B, L]$, which is (1) and is called the Lax equation. L and B are called the Lax pair. The Lax equation guarantees that the flow is an isospectral deformation; namely, that as the potential in (3) deforms according to (1), the spectrum remains unchanged.

The Inverse Scattering Method

The stage is now set to introduce the inverse scattering method (ISM)—or inverse scattering transform (IST)—which is done in three steps. First, one is given the potential $-q(x)$ and from this one defines solutions of (3) and calculates a set of data called the scattering data S . Second, one determines how S evolves as $q(x, t)$ evolves according to (1). Finally, one recovers the potential $-q(x)$ from the time-advanced scattering data S . This is analogous to the set of steps one uses in solving linear PDEs via the Fourier transform, and in a suitable “small” $-q(x)$ limit, S is the Fourier transform. The IST algorithm is

Step 1 : $q(x, 0) \rightarrow S(0)$.

Step 2 : $S(0) \rightarrow S(t)$.

Step 3 : $S(t) \rightarrow q(x, t)$.

Interestingly, IST can be interpreted as a canonical map from the original coordinates $q(x, t)$ to suitable combinations of S that are action-angle variables.

In the first step, one defines two sets of linearly independent solutions $\{\varphi(x, k), \psi(x, -k)\}$, $\{\psi(x, k), \varphi(x, -k)\}$, $\lambda = k^2$ for real values of k (called Jost functions) by their asymptotic properties for all t as $x \rightarrow \pm\infty$,

$$\begin{aligned} \varphi(x, k) &\rightarrow e^{-ikx}, & x \rightarrow -\infty; & \psi(x, k) \rightarrow e^{ikx}, \\ & & x \rightarrow +\infty. & \end{aligned} \quad (6)$$

Because of unit (time-independent) coefficients, the choice of C in (5) for $\varphi(x, t, k)$ is $4ik^3$ and the choice of C in (5) for $\psi(x, t, k)$ is $-4ik^3$. Since (3) is linear, and second order, the pairs of Jost functions are related

$$\varphi(x, t, k) = a(k, t)\psi(x, t, -k) + b(k, t)\psi(x, t, k), \quad (7)$$

where $2ika(k, t)$ and $2ikb(k, t)$ are, respectively, the Wronskians $\varphi(k)\psi_x(+k) - \varphi_x(k)\psi(+k)$ and $\varphi(k)\psi_x(-k) - \varphi_x(k)\psi(-k)$. For a bound state $\lambda_n < 0$ so that $k_n = \sqrt{\lambda_n} = i\eta_n$. Since $\psi(x, t, -k)$ diverges as $x \rightarrow +\infty$ for $\text{Im } k > 0$, the coefficient $a(k, t)$ must vanish for a bound state so that at $\lambda = i\eta_n$, $\varphi(x, t, i\eta_n) = b_n(t)\psi(x, t, i\eta_n)$. Dividing (7) by $a(k, t)$ and using (6), one sees that

$$\begin{aligned} \frac{\varphi}{a} &\rightarrow \frac{1}{a} e^{ikx} \text{ as } x \rightarrow -\infty \\ &\rightarrow e^{ikx} + \frac{b}{a} e^{ikx} \text{ as } x \rightarrow +\infty. \end{aligned} \quad (8)$$

In wave scattering or quantum mechanical language, φ/a is a solution which represents an incoming wave of amplitude unity from $x = \infty$ and waves partially reflected and partially transmitted by the potential $-q(x)$. The coefficients $T(k) = 1/a(k)$ and $R(k) = b(k)/a(k)$ are called the transmission and reflection coefficients, respectively.

It turns out that $\varphi(x, t; k)e^{ikx}(\varphi(x, t; -k)e^{-ikx})$, $\psi(x, t, k)e^{-ikx}(\psi(x, t, -k)e^{ikx})$ and $a(k, t)(a(-k, t))$, originally defined for real k , admit analytic continuation to $\text{Im } k > 0$ ($\text{Im } k < 0$). Each tends to unity as $|k| \rightarrow \infty$. The zeros of $a(k)$, $k_n = i\eta_n$, $n = 1, \dots, N$ are the bound states. There is only a finite number of them. The set of data $S(t) = \{(k_n = i\eta_n, b_n)_1^N; R(k, k \text{ real})\}$ is called the scattering data. From S , $a(k)$ can be found.

In step 2, one uses (5) to calculate the time dependence of $S(t)$. Differentiate (7) with respect to t and use (5) with $C = 4ik^3$ for $\varphi(x, k)$ and $\psi(x, -k)$ and $C = -4ik^3$ for $\psi(x, k)$ to find

$$a_t = 0, b_t = 8ik^3 b. \quad (9)$$

For the bound state at $k_n = i\eta_n$, differentiating $\varphi(x, k_n) = b_n\psi(x, k_n)$ gives $b_{nt} = 8\eta_n^3 b_n$. Therefore, the discrete eigenvalues $k_n = i\eta_n$ are motion constants and $S(t) = \{(k_n = i\eta_n, b_n(0) \exp 8\eta_n^3 t)_1^N; R(k, 0) \exp 8ik^3 t, k \text{ real}\}$.

In step 3, one uses $S(t)$ to reconstruct $q(x, t)$ via the Riemann–Hilbert algorithm, which seeks to reconstruct a meromorphic function for $\text{Im } k > 0$ (think $\frac{\varphi(x, k)}{a(k)} e^{ikx}$) tending to unity as $|k| \rightarrow \infty$, $0 < \arg k < \pi$ and an analytic function for $\text{Im } k < 0$ (think $\psi(x, -k)e^{ikx}$) tending to unity as $|k| \rightarrow \infty$, $-\pi < \arg k < 0$, whose difference on the real axis $\text{Im } k = 0$ is given (think $R(k)\psi(x, k)e^{ikx}$). To achieve this, consider for $\text{Im } k > 0$,

$$I = \frac{1}{2\pi i} \int_{-\infty}^{\infty} \frac{\varphi(x, k') e^{ik'x}}{a(k')(k' + k)} dk' \quad (10)$$

in two ways. First, close the contour at $|k| = \infty$ along $0 < \arg k < \pi$. Second, after using (7), close the contour for that part analytic for $\text{Im } k < 0$ in the lower half-

plane. Identifying the two results, one finds a linear integral equation

$$\begin{aligned} \psi(x, k) e^{-ikx} &= 1 - \sum_{n=1}^N \frac{\gamma_k \psi(x, k_n)}{k + k_n} e^{ik_n x} \\ &+ \frac{1}{2\pi i} \int_{-\infty}^{\infty} R(k) \frac{\psi(x, k') e^{ik'x}}{k' + k} dk', \end{aligned} \quad (11)$$

where $k_n = i\eta_n$, $\gamma_n = b_n(a'(k_n))^{-1}$. The potential $-q(x)$ is recovered from (11) by the formula

$$q(x) = \lim_{k \rightarrow \infty} -2ik \frac{d}{dx} (\psi(x, k) e^{-ikx} - 1). \quad (12)$$

A simple transformation converts (11) into the famous Gel'fand–Levitan equation which, since the mid-1950s, was known as a means for reconstructing potentials from scattering data.

For a special set of initial conditions $q(x, 0)$ called reflectionless potentials, the reflection coefficient $R(k)$ is identically zero. In that case, the Riemann–Hilbert algorithm yields a set of linear algebraic equations found by putting $k = i\eta_r$, $r = 1, \dots, N$ in (11). The simplest is the single soliton solution for which $R(k) = 0$, $a(k) = (k - i\eta)/(k + i\eta)$, $b_1(0) = \exp 2\eta x_0$, $b_1(t) = \exp 2\eta \bar{x}$, $\bar{x} = x_0 + 4\eta^2 t$, $\psi(x, k_1) = e^{-\eta x} (1 + e^{2\eta(\bar{x} - x)})^{-1}$ and $q(x, t) = 2\eta^2 \text{sech}^2 \eta(x - \bar{x})$. Multisoliton solutions can be similarly calculated. They can also be found by a nonlinear superposition principle—the Bäcklund transformation—which is introduced below.

For $q(x, 0) = Q\delta(x)$, $a(k) = (Q + 2ik)/2ik$ and $R(k) = -Q/(Q + 2ik)$, and there is one bound state at $k = iQ/2$. The field consists of a single soliton with $\eta = Q/2s$ and a trailing radiation component. The two components are tied together with the self-similar solution

$$q(x, t) = \frac{1}{(3t)^{2/3}} f\left(\frac{x}{(3t)^{1/3}}\right),$$

which we will meet again when we discuss isomonodromic deformations.

The question: "Is the complete integrability of KdV an isolated miracle or are there lots of integrable PDEs?" was quickly resolved. The pioneering GGKM work of the late 1960s was followed within a few years by the discovery of the complete integrability via ISM of the equally ubiquitous nonlinear Schrödinger (NLS) equation by Zakharov and Shabat and the characterization and integrability via ISM of families of integrable PDEs by Ablowitz, Kaup, Newell, and Segur (AKNS), (See **Ablowitz–Kaup–Newell–Segur system**).

More Space Dimensions

Completely integrable systems in more than one space dimension were also found. Two of the most important were the two-dimensional analogues of the KdV and NLS equations, the Kadomtsev–Petviashvili (KP) and the Benney–Roskes–Davey–Stewartson (BRDS) equations. The KP equation describes the evolution of slightly oblique waves either on shallow water or in a two-dimensional FPU lattice where the linear spring force in one direction is much weaker than it is in the other. It is given by (1) with $\int_{-\infty}^x q_{yy}$ added. It is also the compatibility condition of two linear operators with coefficients depending on $q(x, y, t)$ and its derivatives.

Unexpected connections of integrable PDEs with other exactly integrable models (Ising, Yang–Baxter) were found in the late 1970s and the 1980s. Most notable among them was the discovery by Sato, Miwa, and Jimbo (SMJ) that in the scaling limit, the n -point correlation function of the nearest neighbor, two-dimensional Ising model satisfies a system of very special deformation equations. These express the fact that the monodromy group of an associated linear system, which contains the correlation functions as coefficients, is preserved as the correlation functions change with their arguments. (The monodromy group of matrices encodes information about how the fundamental solution matrix of the linear system changes on taking it through a loop surrounding regular and irregular singular points.) Much of their work has deep connections with classical work on isomonodromic deformations by Ludwig Schlesinger and Paul Painlevé on systems of Fuchsian differential equations (See **Monodromy preserving deformations**) and by Albert Bäcklund on superposition principles for nonlinear equations (See **Bäcklund transformations**). Indeed, soliton theory has had a major impact in many areas of mathematical physics. It has led, for example, to the solution of the Schottky problem of algebraic geometry, to the discovery of quantum groups, to models for quantum gravity, and to useful connections with arithmetic algebraic geometry and, in particular, Jones' polynomials.

Bäcklund Transforms and Hirota's Method

To see the connection with Bäcklund transformations, it is useful to consider further the KdV family of completely integrable PDEs given by

$$q_{t_{2n+1}} = \frac{\partial}{\partial x} L^n q, \quad L = -\frac{1}{4} \partial_x^2 - q - \frac{1}{2} \int_{-\infty}^x dx \, q_x, \\ n = 0, 1, \dots, \quad (13)$$

where $t_{3/4}$ is the t of Equation (1) and $L^0 q = q$. To find them is easy. Write (5) as

$$v_t = A(\lambda; q, q_x, \dots) v - D(\lambda; q, q_x, \dots) v_x + C v, \quad (14)$$

where A, D are polynomials in λ with coefficients depending on q and its x derivatives and C is the normalizing constant. The compatibility of (3) and (14), $(v_{xx})_t = (v_t)_{xx}$, tells one that $A = \frac{1}{2} D_x$ and $q_t = (-\frac{1}{2} \partial_x^3 - 2q \partial_x - q_x - 2\lambda \partial_x) D$. Solve for D as $D = -\lambda^n + D_1 \lambda^{n-1} + \dots + D_n$. Comparing powers of λ determines each D_r in terms of its predecessor as $2 \partial_x D_{r+1} = (-\frac{1}{2} \partial_x^3 - 2q \partial_x - q_x) D_r, \quad r = 0, \dots, n$ with $D_0 = 1$ and D_{n+1} defined by $r = n$. The λ^0 balance gives $q_t = 2 \partial_x D_{n+1} = \partial_x L^n q$.

Equations (13) are a completely integrable family of Hamiltonian commuting flows containing at level $n=1$ the KdV equation. They all share the same constants of motion $\{H_{2r+1}\}_{-1}^{\infty}$ with $H_{-1} = \int_{-\infty}^{\infty} q \, dx, \quad H_1 = \int_{-\infty}^{\infty} \frac{1}{2} q^2 dx, \quad H_3 = \frac{1}{8} \int_{-\infty}^{\infty} (q_x^2 - 2q^3) dx$, each of which serves as the Hamiltonian for one of the flows $q_{t_{2n+1}} = \partial_x \frac{\delta H_{2n+1}}{\delta q}$ where $\frac{\delta H}{\delta q}[q]$ is the variational derivative of $H[q]$ and ∂_x is the skew symmetric symplectic operator. They are also bi-Hamiltonian in that $\partial_x \frac{\delta H_{2n+1}}{\delta q} = (-\frac{1}{4} \partial_x^3 - q \partial_x - \frac{1}{2} q_x) \frac{\delta H_{2n-1}}{\delta q}$. They commute under the Poisson bracket

$$\{H_{2m+1}, H_{2n+1}\} = \int \frac{\delta H_{2m+1}}{\delta q} \frac{\delta}{\delta n} \frac{\delta H_{2n+1}}{\delta q} dx = 0.$$

One consequence of commutativity is that if one begins with the shape $q(x, 0, 0, \dots)$ and evolves q with respect to t_{2n+1} for a time $t_{2n+1}, \quad n = 0, \dots$, in any order, one always obtains the same shape $q(x, t_1, t_3, \dots, t_{2n+1}, \dots)$. This means that the phase shift experienced by any two solitons is the same for each member of the family. Why? Start with the larger, faster moving solution behind the smaller, slower one (the velocity of the soliton of flow n is proportional to η^{2n}). Evolve $q(x, t_{2m+1} = 0, t_{2n+1} = 0)$ via the t_{2m+1} flow for t_{2m+1} time units sufficient for the faster soliton to overtake the slower one and then for t_{2n+1} units via the t_{2n+1} flow. Now do it in the reverse order. Because $q(x, t_{2m+1}, t_{2n+1})$ is the same no matter which order is used, the phase shift must be the same.

A second consequence of commutativity is that one can express the vector made up of the string $L^n q$ as the x derivative of the gradient of a potential which we call $2 \ln \tau(x, t_1, t_3, \dots)$, namely, $L^n q = 2 \frac{\partial}{\partial x} \cdot \frac{\partial}{\partial t_{2n+1}} \ln \tau$. The function $\tau(x, t_1, t_3, \dots)$, called the Hirota τ function, has remarkable properties. It converts each member of the family (13) into bilinear form. For $n=1$, the KdV equation under $q = 2 \frac{\partial^2}{\partial x^2} \ln \tau$ becomes (recall $q_{tt} = q_x$ and take $4t_3 = t$)

$$D_x^2 \tau \cdot \tau = \\ \tau_{xt} - \tau_x \tau_t + \tau \tau_{xxx} - 4 \tau_x \tau_{xx} + 3 \tau_{xx}^2 = 0, \quad (15)$$

where the symbol D_x acting on the ordered pair σ, τ is defined as the limit as $\varepsilon \rightarrow 0$ of $\frac{\partial}{\partial \varepsilon} \sigma(x + \varepsilon) \tau(x - \varepsilon) = \sigma_x \tau - \sigma \tau_x$. For the KP equation, one adds $\tau \tau_{yy} - \tau_y^2$ to the left-hand side of (15). From (15), one can build multisoliton solutions. The solution $\tau = 1$ corresponds to the vacuum state $q = 0$. The solution $\tau = 1 + \exp \theta(x, t)$, $\theta(x, t) = 2k(x - x_0) - 8k^3 t$ corresponds to the single solution solution $q(x, t) = 2k^2 \operatorname{sech}^2 k(x - x_0 - 4k^2 t)$. The next solution in the sequence is $\tau = 1 + \exp \theta_1(x, t) + \exp \theta_2(x, t) + \exp(\theta_1(x, t) + \theta_2(x, t) + A_{12})$, $\theta_j(x, t) = 2k_j(x - \bar{x})$, $x_j = 4k_j^2 t + x_{j0}$, $j = 1, 2$, $A_{12} = 2 \ln \left| \frac{k_1 - k_2}{k_1 + k_2} \right| < 0$, and is a superposition of two solitons with amplitudes $2k_1^2$ and $2k_2^2$, which for large negative t and large positive t are separated with the faster one (assume $k_1^2 > k_2^2$) being on the left(right) when $t = -\infty(+\infty)$. For $t \rightarrow -\infty(+\infty)$, near $x \simeq \bar{x}_2$, the center of the slower pulse, it is the second and fourth (first and third) terms that dominate τ so that for large negative (positive) t , the second soliton looks like

$$2k_2^2 \operatorname{sech}^2 k_2 \left(x - \bar{x}_2 - \frac{1}{2k_2} |A_{12}| \right) \\ \times (2k_2^2 \operatorname{sech}^2 k_2 (x - \bar{x}_2)).$$

The collision shifts the slower soliton back by $\frac{1}{2k_2} |A_{12}|$ and, by a similar argument, the faster soliton ahead by $\frac{1}{2k_1} |A_{12}|$.

What does the interaction look like? For k_1 much greater than k_2 , $|A_{12}| \simeq 0$, and the faster soliton rides adiabatically over the slowly changing slower one. For k_1 greater than but close to k_2 , there is an exchange of identities with the slower soliton assuming the form of the faster one as soon as the trailing edge of the former feels the leading edge of the latter.

But a century before Ryogo Hirota's work in the 1970s (See **Hirota's method**), the works of Bäcklund, Darboux, and Schlesinger had shown how to build, for certain classes of nonlinear equations, complicated solutions from simple ones. Applied to any member of the KdV family, the idea is this. Define

$$q = -u_x = 2\partial_x^2 \ln \tau \quad \text{and} \quad \tilde{q} = -\tilde{u}_x = 2\partial_x^2 \ln \tilde{\tau}$$

Then there are two relations, called Bäcklund transformations, which express $\tilde{u}_x + u_x$ and $\tilde{u}_t + u_t$ as functions of $\tilde{u} - u$ and a new free parameter ζ^2 . Then, if q satisfies KdV, the enriched solution $\tilde{q}$ also satisfies KdV. These expressions take on a beautifully simple form that reveals the algebraic structure underlying the hidden symmetries of the KdV family when they are expressed in terms of τ functions as $\tilde{\tau} = \tau v$ where $v(x, \zeta^2)$ solves (3) with the q corresponding to τ and $\lambda = \zeta^2$. But one can also express v as a combination of $\frac{X(\zeta)\tau}{\zeta}$ and $\frac{X(-\zeta)\tau}{\zeta}$,

where the operator

$$X(\zeta) = \exp \left(i \sum_0^\infty \zeta^{2k+1} t_{2k+1} \right) \\ \times \exp \left(\sum_0^\infty \frac{i}{(2k+1)\zeta^{2k+1}} \frac{\partial}{\partial t_{2k+1}} \right),$$

so that $\tilde{\tau} = \tau_{\text{new}} = (AX(\zeta) + BX(-\zeta))\tau_{\text{old}}$.

For example, choose $\zeta = i\eta$. Then if $\tau_{\text{old}} = 1$, $\tau_{\text{new}} = Ae^\theta + Be^{-\theta} = 2\sqrt{AB} \cosh(\theta - \theta_0)$, where $\frac{A}{B} = e^{2\theta_0}$ and $\theta = \sum_0^\infty (-1)^k \eta^{2k+1} t_{2k+1}$ and τ_{new} is the one soliton solution. Because of the logarithm, we can also write $\tau_{\text{new}} = (1 + \beta Y(\zeta))\tau_{\text{old}}$ where $Y(\zeta)$ is called the vertex operator

$$Y(\zeta) = \exp \left(-2i \sum_0^\infty \zeta^{2k+1} t_{2k+1} \right) \\ \times \exp \left(\sum_{k=0}^\infty \frac{2}{i(2k+1)\zeta^{2k+1}} \frac{\partial}{\partial t_{2k+1}} \right), \quad (16)$$

which has the property that $Y(\zeta) \cdot Y(\zeta') 1 = 0$ if $\zeta = \zeta'$. Thus $Y^2 = 0$ and we can replace $1 + \beta Y(\zeta)$ by $\exp \beta Y(\zeta)$. The Bäcklund transformation is therefore

$$\tau_{\text{new}} = \exp \beta Y(\zeta) \cdot \tau_{\text{old}} \quad (17)$$

namely, the action of the “group” (infinite-dimensional groups are not rigorously defined) element corresponding to the algebraic element $Y(\zeta)$, which can be expressed as a Laurent series $\sum_{-\infty}^\infty Y_{2k+1} \zeta^{2k+1}$. The coefficients Y_{2k+1} obey a nontrivial set of commutator relations that form an infinite dimensional, graded Lie algebra (Kac–Moody algebra), the central extension of the loop algebra of $\mathfrak{sl}(2, \mathbb{C})$. Under repeated application of (17), solutions of KdV trace out the orbit of the highest weight vector $\tau = 1$ in the basic representation of the Kac–Moody algebra. The algebra acts as an algebra of symmetries. There is also a complementary treatment where the algebra is used as the phase space on which there is defined both a natural Poisson bracket and Hamiltonian vector field.

Other Topics

Multisoliton solutions of the KdV family are a special case of finite gap solutions. The latter are defined by adding a nonlinear, constant coefficient ODE called the Lax–Novikov equation

$$\sum_0^N a_{2r+1} (L^r q)_x = \sum_0^N a_{2r+1} q_{t_{2r+1}} = 0 \quad (18)$$

as a constraint on (3) and (14). To illustrate the basic idea, assume traveling wave solutions

$$q(x, t) = q(x - ct) \text{ satisfy } -cq_x + (q_{xx} + 3q^2)_x = 0,$$

which is (18) with $a_1 = -c$, $a_3 = 4$, and $a_{2k+1} = 0$, $n > 1$. The Lax–Novikov equation, together with (3) and (14) gives rise to a Riemann surface, the analogue of the spectrum for potentials decaying at infinity, $y^2 = \prod_{j=1}^N (\lambda - \lambda_j)$ which remains invariant on the finite gap solution family. The τ function for the general N gap solution is the Riemann theta function.

Another class of solutions, the multiphase self-similar solutions, is found by attaching a nonlinear non-autonomous ODE

$$a_0 q + \sum_0^N a_{2r+1} t_{2r+1} (L^r q)_x \\ = a_0 q + \sum a_{2r+1} t_{2r+1} q_{t_{2r+1}} = 0 \quad (19)$$

as a constraint to (3) and (14). It is closely related to the string equation of modern physics, and it leads to a system of linear ODEs for

$$\lambda \frac{\partial}{\partial \lambda} \left\{ \begin{array}{l} v(x, t_{2r+1}, \lambda) \\ v_x(x, t_{2r+1}, \lambda) \end{array} \right\}$$

with coefficients depending on self-similar scalings of q and its derivatives. Solutions of the multiphase self-similar family are isomonodromic deformations of this system of ODEs in that they leave the monodromic structure invariant. At $\lambda = \infty$, an irregular singular point, the monodromic structure is expressed in terms of Stokes multipliers; at $\lambda = 0$, a regular singular point, the monodromy is that of a simple pole. Members of this family include the Painlevé equations.

For example, (19) with $a_0 = -2$, $a_1 = -1$, $a_3 = 3$, $t_3 = t - 2q - xq_x + 3t(q_{xx} + 3q^2)_x = 0$ which forces $q(x, t)$ to have the form

$$\frac{1}{(3t)^{2/3}} f\left(X = \frac{x}{(3t)^{1/3}}\right),$$

which satisfies an ODE that is a close cousin of the second Painlevé equation. This solution plays a key role in joining the soliton component of the solution with the trailing wave-like radiation. Isomonodromic deformations provide the link between soliton equations and the exactly solvable models of statistical physics. For example, the two-point correlation function for the nearest-neighbor Ising model in the scaling limit satisfies the third Painlevé equation.

The existence of so many completely integrable systems of physical interest (KdV, Boussinesq, nonlinear Schrödinger, derivative nonlinear Schrödinger, massive Thirring, sine-Gordon, Maxwell–Bloch with inhomogeneous broadening, KP, BRDS, three-wave scattering, Raman scattering) leads one to ask how important to applications these integrable models are. In the set of all PDEs, they are of measure zero. On the other hand, there are two reasons for their importance. The first is that many systems such as shallow waves traveling over a channel of slowly varying depth can be treated

as perturbations of PDEs integrable by ISM, and there are simple algorithms for computing how the previously constant action variables slowly evolve. The second reason is more subtle and remains to be rigorously proven. Many of the equations of physical interest arise as asymptotic approximations, as reductions of more complicated systems assuming (as one does in deriving KdV) weak nonlinearity and weak dispersion, or (as one does in deriving NLS) weak nonlinearity and strong dispersion of an almost monochromatic wavepacket. If the process of reduction preserves integrability, then as long as there is one integrable equation among the class that reduces to the universal equation of interest, the reduced equation will also be integrable.

Finally, how does one test for integrability? How does one uncover the hidden symmetries, the algebraic structure of a PDE or ODE? There is yet no foolproof method that works in all circumstances. As in the original discovery of the integrability of KdV, serendipity often plays the main role. Two of the more promising semi-algorithmic approaches are the Painlevé test (the location of any algebraic, logarithmic or essential singularity is independent of initial conditions and only the location of poles can depend on arbitrary constants of integration), and the Wahlquist–Estabrook method, which seeks to uncover the hidden symmetries by embedding the equation of interest as an integrability condition of a pair of linear systems whose algebraic structure it is the goal of the method to find. Each has its advantages and each has proven to be successful in extracting the appropriate Lax pair in several contexts. But the challenge of determining a foolproof method to determine whether a particular equation is integrable is still open.

ISING MODEL

The Ising or Lenz–Ising model was introduced by Wilhelm Lenz in 1920 as a simplified model of a ferromagnet. Lenz's student Ernst Ising studied the one-dimensional case (a linear chain of coupled magnetic moments) for his doctoral dissertation at the University of Hamburg, and his results published in 1925 showed the absence of a phase transition between a ferromagnetic and paramagnetic state. In 1942, Lars Onsager applied an ingenious mathematical method to the two-dimensional model and showed analytically the existence of a phase transition in the absence of an external magnetic field. Interest in the model has increased in recent years as it became the foundation for modeling changes of state in new areas such as spin glasses and neural networks. In 1975, David Sherrington and Scott Kirkpatrick introduced long-range competing interactions in the model and showed the emergence of a new type of glassy order, while John Hopfield in 1982 used the connection between spins and neurons in extending the Ising model into a model of neural networks.

The original motivation for the introduction of the model came from the knowledge that certain metals, such as iron, are ferromagnetic; that is, they form macroscopic domains with nonzero magnetization when the temperature is less than a characteristic Curie temperature (T_c), but this long-range order is lost at temperatures $T > T_c$. Because magnetic properties of atoms are a result of the orbital angular momentum as well as spin of their electrons, the existence of macroscopic size domains with nonzero magnetization stems from mutual alignment of permanent atomic dipole moments induced by dipole-dipole interactions. The Lenz–Ising simplification ignores quantum mechanics and assigns to an atom located in crystal site i a magnetic moment or “spin” S_i that takes only two values, namely, $S_i = \pm 1$. The energy or Hamiltonian for the system of N spins is

$$H = -\frac{1}{2} \sum_{i,j=1}^N J_{ij} S_i S_j - \sum_{i=1}^N B_i S_i, \quad (1)$$

where J_{ij} is the interaction between spins at sites i and j ; respectively; B_i is a local magnetic field at site i ; and the sums extend independently over all N sites. Any of the 2^N spin configurations can be thought of as a chemical solution of two species with N_+ and $N_- = N - N_+$ spins in up and down states, respectively, with number densities $n_{\pm} = N_{\pm}/N$; the entropy of this state is determined by the number of ways N spins are

partitioned in up and down configurations, giving

$$S = -Nk_B (n_+ \ln n_+ + n_- \ln n_-). \quad (2)$$

Furthermore, the density of $++$, $--$, and $+-$ pairs that determine short-range order is approximated in the Bragg–Williams approximation respectively, by n_+^2 , n_-^2 , and $2n_+n_-$. Thus, Equation (1) becomes

$$H = -\frac{1}{2} z N J (n_+^2 + n_-^2 - 2n_+n_-) - N B (n_+ - n_-), \quad (3)$$

where only interactions of strength J between z nearest-neighbor spins are included. Introducing the macroscopic magnetization $M = N_+ - N_- = N(n_+ - n_-)$, expressing the densities as $n_{\pm} = (1 \pm M/N)/2$, and substituting in the energy and entropy, respectively, one obtains

$$\begin{aligned} H &= -\frac{z J M^2}{2N} - M B \\ S &= N K \left[\ln 2 - \frac{1}{2} \left(1 + \frac{M}{N} \right) \ln \left(1 + \frac{M}{N} \right) \right. \\ &\quad \left. - \frac{1}{2} \left(1 - \frac{M}{N} \right) \ln \left(1 - \frac{M}{N} \right) \right] \end{aligned} \quad (4)$$

The thermodynamics of the model is now completely determined from the minimization of the Helmholtz free energy $F = H - TS$ with respect to the magnetization M at constant external field B and temperature T . It yields

$$\frac{M}{N} = \tanh \beta \left(B + z J \frac{M}{N} \right), \quad (5)$$

where $\beta = 1/k_B T$. Equation (5) is identical to that obtained through the Weiss mean field theory predicting, after linearization and for zero external field, a Curie temperature determined by $k_B T_c = zJ$.

If the interaction J_{ij} is not fixed but taken to be random, distributed according to a Gaussian with mean J_0/N and variance J^2/N , then

$$P(J_{ij}) = \left(\frac{N}{2\pi J^2} \right)^{1/2} \exp \left[- \left(J_{ij} - \frac{J_0}{N} \right)^2 \frac{N}{2J^2} \right]. \quad (6)$$

The resulting Ising model is referred to as the Sherrington–Kirkpatrick model, and its low-temperature phase at zero-external-field is a spin glass. This phase is not characterized by the long-range order typical in ferromagnets but by partial system freezing in time showing persistent but spatially random configurations whose thermodynamic signature is a sharp cusp in the zero field cooled susceptibility. A spin glass is typically characterized by metastability, frustration, and slow relaxation resulting from the multiple high barriers (introduced by disorder in the

free energy) that force the system to remain trapped in local free energy minima for long times.

Introducing some changes in the Ising spin-glass model and with proper interpretation, one obtains a model for a network of neurons. Ising spins are now states of a neuron found in a firing ($S_i = +1$) or inhibitory state ($S_i = -1$), the interaction elements J_{ij} are synaptic strengths between neurons while the external field depends on a neuron firing threshold potential. In the learning mode, the network stores information on patterns in the synaptic strengths, while in the retrieval mode, these patterns are accessed when the network is exposed to partial information on the desired memories. If $S^\nu \equiv \{S_1^\nu, S_2^\nu, \dots, S_N^\nu\}$ (for $\nu = 1, \dots, p$) represent p patterns of N neurons, employment of the following version of Hebb's rule:

$$J_{ij} = \frac{1}{N} \sum_{\nu=1}^p S_i^\nu S_j^\nu \quad (7)$$

stores the p patterns in memory. In the Hopfield model for $p/N \leq 0.14$, these states, as well as several other spurious ones, become attractors to the evolution flow of neuron updating rules. Whenever a spin-glass phase is present, either alone or in coexistence with the memory states, information retrieval is corrupted.

While the phase diagrams of Ising spin glasses and neural networks are quite complex, the one determined analytically by Onsager for the two-dimensional Ising model with nearest-neighbor interaction J is much simpler, demonstrating the presence of a Curie temperature at $k_B T_c \approx 2.269J$ with a low-temperature ferromagnetic phase. This shows that even though

quite simple, the Ising model contains the essential features of the problem that motivated its introduction, the ferromagnetic-paramagnetic transition. The absence of a transition in one dimension as found by Ising can be understood qualitatively by the following argument of Wannier. Energy equal to $2J$ can introduce a spin down defect in an ordered chain of $N + 1$ spins that are all in state up, and this can be done in N ways resulting in entropy $k_B \ln N$. The free energy for this change is $\Delta F = 2J - k_B T \ln N$ and favors always the entropic term except at $T = 0$; thus, there cannot be long-range order in one dimension at finite temperatures.

JOSEPHSON JUNCTION ARRAYS

Josephson junction arrays (JJAs) consist of islands of superconductor arranged in an ordered lattice, coupled by Josephson junctions. Large JJAs are useful model structures for studying the dynamics of coupled nonlinear oscillators, phase transitions, frustration effects, vortex dynamics, and macroscopic quantum phenomena (Newrock et al., 2000).

JJAs are generally divided into classical arrays ($E_J/E_C \gg 1$) and quantum arrays ($E_J/E_C \ll 1$), depending on the ratio of the Josephson energy, E_J , to the charging energy, E_C (Fazio & van der Zant, 2001). Classical JJAs can be divided into overdamped arrays ($\beta_C \ll 1$) and underdamped arrays ($\beta_C \gg 1$), referring to the fact that the equation of motion for a single Josephson junction is identical to a damped pendulum. The dividing line is determined by the McCumber parameter, β_C , which defines the amount of damping in terms of the junction capacitance and resistance.

Modeling of classical JJAs is essentially based on solving a system of coupled ordinary differential equations for the superconducting phase differences φ_n of Josephson junctions that constitute the array. Typically, JJAs are fabricated using photolithography and the standard fabrication processes for superconductive electronics. They are very well characterized, leading to an interesting synergy between experiments, theory, and simulations.

The properties of JJAs depend on their dimensionality and the way Josephson junctions are connected. In the series one-dimensional (1-d) JJAs shown in Figure 1a, there is no direct interaction between Josephson junctions. The junctions can be coupled, for example, via a load resistor connected between the extremities of the array. Under certain conditions (Jain et al., 1984), when biased by a bias current flowing along the array, Josephson junctions perform coherent oscillations.

Parallel 1-d arrays shown in Figure 1b have inherent mutual coupling between Josephson junctions due

to screening currents and magnetic flux quantization in superconducting loops. Such an array is essentially similar to a long Josephson junction, and it is described by the discrete sine-Gordon (SG) model. Due to the similarity between the discrete SG and continuous SG models, properties of vortices in parallel 1-d JJAs are similar to those of Josephson vortices (solitons called fluxons) in long Josephson junctions (Ustinov & Parmentier, 1996; Watanabe et al., 1996).

The two-dimensional (2-d) JJA illustrated in Figure 1c has attracted a great deal of interest as it is isomorphic to a 2-d XY spin system, which is a 2-d lattice of spins free to rotate in the XY plane. In its simplest form, the Hamiltonian of an array can be written as

$$H = - \sum_{(n,m)} E_J \cos(\varphi_m - \varphi_n - f), \quad (1)$$

where $\langle n, m \rangle$ means summing over nearest neighbors and f is the frustration factor depending on the externally applied magnetic field. It should be noted that model (1) is valid only under the condition that both E_J and the array cell size are small enough, i.e., that inductance effects play no role. In practical JJAs, this is typically not the case and these effects significantly complicate JJA dynamics.

Figure 1. Schematic view of (a) 1-d series JJA; (b) 1-d parallel JJA; (c) 2-d JJA.

Figure 2. (a) Micro-photograph of a Josephson ladder (Binder et al., 2000). (b) The equivalent circuit of the ladder.

Starting from the mid-1990s, a special type of JJA called the Josephson ladder has received much interest. The ladder is essentially one row of cells cut from the standard 2-d JJA. Floría et al. (1996) studied a ladder driven by an ac bias current and found both oscillating and rotating localized modes. Such intrinsically localized modes, often called discrete breathers, are spatially localized time-periodic dynamical states that occur in various nonlinear lattices. The oscillating modes in Josephson arrays are difficult to detect experimentally as they are accompanied by zero average dc voltage. In contrast to oscillating discrete breathers, rotating discrete breathers induce a localized nonzero dc voltage and can be easily measured. Moreover, rotating discrete breathers can also be supported by a dc bias current. Experiments that followed the theoretical proposals successfully demonstrated dynamical localization in the form of discrete breathers in JJA (Ustinov, 2001).

There are several useful applications of JJA. At microwave frequencies, Josephson junctions can be used as sources and detectors of radiation. The Josephson relation $\Phi_0 \nu = V$ (where $\Phi_0 = h/(2e) = 2.07 \times 10^{-15}$ Vs is the magnetic flux quantum) states that at constant voltage V , the current through the junction will oscillate with a frequency ν , proportional to V . Utilizing this unique property, Josephson junction arrays have for the last two decades been studied as microwave sources (Darula et al., 1999). The advantages of using arrays as opposed to junctions are higher power outputs and better impedance matching to typical loads. Another important application of JJA, based on the same equation, is to define the voltage standard. Since frequency can be measured extremely accurately, locking Josephson junctions to a microwave source provides excellent accuracy for measuring the voltage. Using a series JJA instead of a single Josephson junction allows the upper voltage level to be brought from less than a millivolt up to the range of several volts.

JOSEPHSON JUNCTIONS

Predicted theoretically by Brian Josephson in 1962, the Josephson junction (JJ) consists of two superconductors that are so weakly coupled that the Cooper pairs may quantum mechanically tunnel between the superconductors without destroying the integrity of their individual macroscopic wave functions, Ψ_1 and Ψ_2 . A typical example is the trilayer tunnel junction (see Figure 1) consisting of two overlapping niobium (Nb) thin films separated by a thin (2–5 nm) insulating layer of aluminum oxide (Al_2O_3).

Extremely fast and highly nonlinear, the JJ is described by the two Josephson equations

$$I = I_c \sin \phi, \quad (1)$$

$$\frac{\partial \phi}{\partial t} = \frac{2\pi}{\Phi_0} V, \quad (2)$$

where I is the pair-current through the junction. The critical current I_c is a constant parameter given by the materials, the barrier, and the geometry of the structure. $\Phi_0 = h/2e$ is the flux quantum, $\phi = \theta_1 - \theta_2$ is the difference between the phases θ_1 and θ_2 of Ψ_1 and Ψ_2 , respectively, and V is the voltage across the junction. These equations assume a constant current density over the junction area.

Figure 1. Typical Josephson tunnel junction consisting of two superconducting thin-films separated by a very thin insulating oxide layer.

If one applies a dc bias current $I < I_c$ to the junction, the phase difference ϕ of the macroscopic wave functions automatically adjusts itself so that Equation (1) is satisfied; i.e., the junction remains in the zero-voltage state carrying a supercurrent up to the critical current. For $I \geq I_c$, the junction switches to the voltage state, and ϕ oscillates in time according to the second Josephson equation.

If the junction is supplied with a constant voltage, V_{DC} , the phase difference increases steadily with time, and the junction current oscillates with the frequency

$$f = \frac{1}{\Phi_0} V_{DC}; \quad (3)$$

that is, the junction functions as a voltage controlled oscillator (VCO) that may generate microwave power into the gigahertz range. (The pre-factor $1/\Phi_0 \approx 0.5 \text{ GHz}/\mu\text{V}$.)

The capacitance between the two electrodes in Figure 1 shunts the Josephson tunneling and leads to hysteresis in the current-voltage characteristic (I - V curve) as shown in Figure 2a. Starting at zero and increasing the bias current, there is a vertical supercurrent (zero-voltage state) up to I_c where the junction switches (horizontally) to the steep so-called quasi-particle curve (near 2.7 mV), which reflects the superconducting gap of the two niobium electrodes. The quasi-particle curve is followed both when the bias current is further increased and when the current is returned to $I = 0$. The hysteretic I - V curve is point-symmetric around $(V, I) = (0, 0)$.

The I - V curve near the gap is strongly nonlinear and temperature dependent. Tunnel junctions biased close to the knee are used as low-noise bolometers to detect broad band signals in the millimeter and sub-mm range. Due to its strong nonlinearity, heterodyne receivers based on this SIS-mixer (superconductor-insulator-superconductor) can be operated near the quantum limit ($hf \approx k_B T$). The SIS-mixer may be pumped by the microwave signal emitted from a long JJ (see below). Most modern radio-telescopes employ SIS-mixers for spectral measurements in the frequency range 10–1000 GHz.

Figure 2b shows the I - V curve when a microwave signal is applied to the junction. The supercurrent

Figure 2. dc current-voltage characteristic of Nb/Al₂O₃/Nb trilayer Josephson tunnel junction at 4.2 K. Note the supercurrent in the zero-voltage state and the steep gap structure near 2.7 mV. (a) No applied microwaves and (b) with applied microwaves. The small vertical zero-crossing steps are equidistantly spaced with a voltage difference of $\Delta V = hf/2e$. These nonlinear quantum phenomena allow for the practical construction of the Josephson voltage primary standard.

is suppressed and small equidistantly spaced replica appear as vertical (Shapiro) steps with a voltage difference of $\Delta V = hf/2e$. These zero-crossing steps and the fact that voltage and frequency are related only through fundamental constants allow for the practical realization of the Josephson voltage primary standard. When pumped by a 70 GHz signal, $\Delta V \approx 140 \mu\text{V}$; thus a small chip with more than 20,000 dc series connected JJs can generate a reference voltage of 10 V with an accuracy of 0.1 nV. Josephson junctions are strongly nonlinear elements which when pumped by external high-frequency signals may not only generate very high-numbered higher harmonics but also via parametric processes generate both even and odd subharmonics (e.g., period-doubling bifurcations) and chaos. The stability of the Josephson voltage standard is limited by chaotic behavior.

JJs are highly sensitive to magnetic fields. The gradient of the phase difference ϕ is proportional to the magnetic field applied in the plane of the junction, and for constant current density the net critical current is zero each time ϕ has a twist of 2π , which happens when the flux Φ threading the junction is exactly one flux quantum Φ_0 . Included in a superconducting ring, JJs constitute the so-called Superconducting Quantum Interference Device (SQUID), which is used, for example, for magnetoencephalographic measurements of electrical activity in the human brain.

The magnetic twist of the phase difference along the junction also leads to the so-called Fiske steps. These are nearly constant-voltage steps in the I - V curve at voltages $V_{FSn} \approx \Phi_0 c_s / 2L$, where $n = 1, 2, \dots$ and L is the junction length perpendicular to the magnetic field. Also, c_s is the Swihart velocity of electromagnetic waves propagating in the junction (about 3% of the light velocity in vacuum). The physical mechanism is as follows. The Josephson oscillations at the voltages V_{FSn} excite standing electromagnetic waves inside the junction (cavity) with wavelengths $\lambda_n = 2L/n$ and resonance frequencies $f_n = c_s/\lambda_n$. Whenever the spatial twist in $\Phi(x)$ fits to the n th mode of the standing wave, there is a strong resonant nonlinear interaction

that phase-locks the Josephson oscillation at f_n , giving Fiske steps at voltages V_{FSn} .

Until now we have considered only JJs with small dimensions compared with the so-called Josephson penetration length λ_J , which is of the order of 10 μm . Longer tunnel junctions are well modeled by the perturbed sine-Gordon (SG) equation. If we consider a linear one-dimensional (1-d, x -direction) junction with dc current bias, the SG equation in normalized units reads

$$\phi_{xx} - \phi_{II} = \sin \phi + \alpha \phi_t - \eta, \quad (4)$$

where the normalized magnetic field $\kappa_{1,2}$ (perpendicular to the x -direction) enters as the boundary condition

$$\phi_x(0, t) = \kappa_1 \quad \text{and} \quad \phi_x(l, t) = \kappa_2, \quad (5)$$

specifying the magnetic field at the two ends of the junction. The normalized bias current η here is assumed to be evenly distributed along the junction (overlap geometry). In the above equations, time t is normalized to the inverse maximum plasma frequency, ω_0 , length x to λ_J , currents to the maximum critical current, I_c , and magnetic fields to the critical field, H_c , needed to force the first fluxon into the junction. Magnetic fields can only enter the junction in the form of fluxons, which are individual soliton-like localized 2π phase shifts each containing one flux quantum Φ_0 .

Many solutions to the nonlinear SG equation have been found by numerical integration. For zero magnetic field and low values of the damping coefficient α , fluxons oscillate resonantly back and forth inside the junction driven by the Lorentz-like force from the bias current. This gives rise to a 4π phase shift per period and leads to the so-called zero-field steps, which are nearly constant-voltage steps located at voltages $V_{ZFSn} \approx n\Phi_0 c_s L$, $n = 1, 2, \dots$ in the I - V curve. Note that zero-field step voltages are twice as large as the voltages of the Fiske steps discussed above for short junctions.

For every fluxon collision at $x = l$ (where l is the normalized junction length), a small electromagnetic field is emitted and the junction may be used as a microwave oscillator when biased on either a Fiske step or a zero-field step, but applications of this resonant soliton oscillator (RSO) are rather limited. First, the resonance frequencies are fixed (given by L and c_s) and the tunability is very small (steep steps). Second, the emitted power is relatively low and has high harmonic content (fluxon collision delta-function-like in time domain). However, due to its frequency stability and rather narrow linewidth, the RSO may be used as an on-chip clock oscillator.

When a stronger external magnetic field is applied (e.g., from a dc current, I_{CL} , in an overlaying control line), the junction will contain many fluxons, and since the fluxons repel each other, they will form an equidistant chain. Under a very strong field, the fluxons are forced so close to each other that the phase gradient

becomes nearly uniform and proportional to the field strength. (One may compare the phase variation to a household corkscrew where the pitch is given by the applied magnetic field.) If a dc bias current I_B (uniformly distributed along the x -direction) is also applied to the junction, the fluxon chain is forced to move with constant velocity along the junction leading to a unidirectional flux flow through the junction. In our analogy, the bias current forces the corkscrew to rotate with constant angular velocity. The total phase shift per second and, thus, the frequency of the microwave signal emitted at $x = l$ can therefore be adjusted independently by the dc bias current (rotation) and the dc magnetic field (pitch). In the I - V curve, one observes a flux flow step (FFS) where the voltage, V_{FFS} , depends on both I_B and I_{CL} . Because the pitch for a dense chain of fluxons increases proportional to the magnetic field, V_{FFS} , the oscillator frequency in this limit depends linearly on I_{CL} for fixed I_B .

This explains the dynamics of the important flux flow oscillator (FFO). Its easy tunability not only permits wide band frequency coverage but also allows for accurate phase locking of the FFO. The power emitted from the FFO depends in a complicated way on the junction parameters as well as on I_B and I_{CL} , but with appropriate microwave design the power is sufficient to pump an SIS-mixer placed on the same chip. In 2002, a fully superconducting integrated receiver (SIR) with FFO, stripline circuit, SIS-mixer, and antenna (all placed on a $5 \times 5 \text{ mm}^2$ chip) has been operated in phase-locked mode up to 712 GHz with a frequency resolution of less than 1 Hz relative to the reference oscillator used in the phase-locking loop. At 500 GHz the noise temperature was less than 100 K, just above the quantum limit. The low-noise in combination with the high-frequency resolution in the submillimeter frequency range is very promising for spectral investigations in astronomy, chemistry, and biophysics.

Numerical simulations of the SG equation have confirmed that the unidirectional flux flow mode can also be sustained for very large values of the damping parameter α . Often the damping per normalized length $\alpha l > \pi$ is used to define the flux flow range. For low values of αl the FFS consists of a distinct Fraunhofer pattern of Fiske steps localized in the vicinity of the average FFS voltage given by I_B and I_{CL} . The correct boundary conditions, the geometry, and especially the paths along which the two bias currents are supplied to the junction are very important for the free-running linewidth of the FFO and thus for the practical implementation of the SIR.

For simplicity, we have restricted ourselves to a single Josephson junction with linear 1-d geometry. Considerable work has been devoted to 1- and 2-d arrays of both short and long junctions, and vertically stacked junctions (*See Josephson junction arrays; Long Josephson junctions*). Many structures and

circuits have been fabricated in both low- T_c and high- T_c superconductors. The 1-d long Josephson junction with annular geometry is of considerable interest, not least because the cyclic boundary conditions are combined with flux quantization and flux trapping. Whole families of *single flux quantum* (SFQ) and *rapid single flux quantum* (RSFQ) electronics based on propagation of single fluxons in superconducting circuits containing Josephson junctions and SQUIDS (See **Superconducting quantum interference device**) have been developed and partially tested for applications. Josephson junction science and technology now is mature, and many applications are waiting to be implemented in future electronics.

JUMP PHENOMENA

Jump phenomena or surfaces of discontinuity occur when a field or gradient of a field exhibits finite jumps (discontinuities) due to the system changing nature (such as a liquid-gas interface) or the geometry of the domain changing abruptly in a given hyperplane (such as an acoustical tube with an abrupt widening). A particularly dramatic example of a hydraulic jump (see Figure 1) appeared regularly on the river Seine early in the 20th century.

In nature, systems are often governed by conservation laws of the various quantities. For example, for a fluid, we can write equations for the conservation of mass, momentum, and energy, and in an electrical system, current is conserved. There may be a hierarchy of these laws so when the system is perturbed the lower order ones are approximately maintained while the higher order ones are clearly broken.

Following the discussion of Landau (Landau & Lifschitz, 1959), one can classify discontinuities in two main groups. Let us illustrate this with the example of a continuous medium for which mass flux, momentum flux, and energy flux are continuous across a discontinuity. In the first case, mass flux is zero across the discontinuity, implying that the tangential derivative of the velocity has a jump. This is called a tangential discontinuity, a familiar example being the ocean surface separating water circulation from wind circulation. In the other case, called a shock wave (See **Shock Waves**), mass flow is nonzero, implying a jump in the velocity normal to the discontinuity. The existence of such discontinuous fields is strongly connected to the hyperbolic nature of the system of equations for which wave fronts can propagate along definite directions (characteristics).

In reality, the velocity normal to the interface is not discontinuous but varies on a very small scale due to viscosity and damping which are not taken into account in the original model. In particular, energy is dissipated in such an event so that the energy flux is not conserved. A way to remove this difficulty is to assume a given dissipation and modify the energy jump condition. It is remarkable that such modified jump conditions can describe accurately the state of a system where dissipation occurs even without an accurate description of the (microscopic) dissipation mechanism.

Examples

Example (i)

As an example of a normal discontinuity (shock wave), consider a one-dimensional compressible fluid flow. The conservation of mass and momentum of the fluid can be written as

$$\rho_t + (\rho v)_x = 0, \quad (1)$$

$$v_t + vv_x + \frac{c^2}{\rho} h_x = 0, \quad (2)$$

where the subscripts indicate partial derivatives, ρ is the gas density, v the velocity along the x axis, and $c(\rho)$ is the velocity of sound.

In 1860, Bernard Riemann obtained a solution of this system by assuming a single dependence of the two fields $\rho(\alpha(x, t))$ and $v(\alpha(x, t))$ on an unknown function α . He obtained the compatibility condition linking ρ and v :

$$v = \pm \int \frac{c(\rho)}{\rho} d\rho, \quad (3)$$

and showed that α should satisfy the one-dimensional partial differential equation

$$\alpha_t + (v \pm c)\alpha_x = 0, \quad (4)$$

Figure 1. A tidal bore (or *mascaret*) on the Seine at Quillebeuf, France. The site is 19 km from the mouth of the river, where tides up to 10 m occur. Due to dredging in the 1960s, this striking nonlinear phenomenon has disappeared. (Courtesy of J.J. Malandain.)

whose formal solution is $\alpha = f(x - (v \pm c)t)$. This indicates that given values of v and ρ move to the right along the characteristic lines $x = (v \pm c)t$ at speeds $v \pm c$, allowing shock waves across which the velocity and density fields are discontinuous. Consequently, an initial condition with $v > c$ will only propagate to the right, whereas if $v < c$, it will propagate over the whole domain.

Consider how to derive jump conditions; from (1). Assume $c^2 = \rho g$ where g is a constant; this is not physical in the context of gases but it simplifies the derivation. The conservation of the mass flux is obtained by integrating the first equation on a small domain $-\varepsilon < x < \varepsilon$ centered on $x = 0$; thus,

$$\int_{-\varepsilon}^{\varepsilon} \rho_t dx + [\rho v]_{x=-\varepsilon}^{x=\varepsilon} = 0. \quad (5)$$

Assuming that ρ_t has a finite discontinuity at $x = 0$, we obtain in the limit $\varepsilon = 0$

$$[v\rho] = 0. \quad (6)$$

The momentum conservation law is obtained by examining the time evolution of the average momentum ρv :

$$(\rho v)_t + \left(\rho v^2 + \frac{g\rho^2}{2} \right)_x = 0. \quad (7)$$

The last conservation law involves the total energy e of the fluid, which is the sum of the kinetic and potential energy

$$(\rho v^2 + g\rho^2)_t + (\rho v^3 + 2g\rho^2 v)_x = 0. \quad (8)$$

Proceeding in a similar way as for the mass flux, we obtain jump conditions for the momentum and energy of the fluid so the entire set of jump conditions are

$$\begin{aligned} [v\rho] &= 0, \quad \left[\rho v^2 + \frac{g\rho^2}{2} \right] = 0, \\ [v^3\rho + 2g\rho^2 v] &= 0. \end{aligned} \quad (9)$$

Example (ii)

The second kind of discontinuity occurs when considering compression waves in an inhomogeneous beam made of two beams of different materials soldered at some point. The equation describing the displacement u is the one-dimensional generalized wave equation

$$\rho \sigma u_{tt} - (\sigma E u_x)_x = 0, \quad (10)$$

where σ is the beam section, ρ its density, and E the Young modulus such that $E = E_l$ for $x < 0$ and $E = E_r$ for $x > 0$. To obtain the jump condition at $x = 0$, one integrates equation (10) over a small domain $-\varepsilon < x < \varepsilon$ to obtain

$$\int_{-\varepsilon}^{\varepsilon} dx \rho \sigma u_{tt} - [\sigma E u_x]_{x=-\varepsilon}^{x=\varepsilon} = 0. \quad (11)$$

Now consider the limit $\varepsilon = 0$, assuming the displacement u to be continuous across $x = 0$. The first term is the acceleration which should tend to zero. The second term is the stress, and relation (11) shows that it too should be continuous. At $x = 0$, we then have the following relations:

$$u_l = u_r, \quad E_l u_x|_l = E_r u_x|_r, \quad (12)$$

so the gradient u_x exhibits a finite jump.

Hydraulic Jumps

Shallow water flows for which the depth h_0 is much smaller than the length l are governed by the following equations for the water elevation h and velocity v in the direction of propagation (Landau & Lifschitz, 1959)

$$h_t + (hv)_x = 0, \quad (13)$$

$$v_t + vv_x = -gh_x, \quad (14)$$

which are the same as (1) if we write $h = \rho$ and assume $c^2 = \rho g = gh$.

Consider a so-called hydraulic jump solution occurring, for example, when a dam breaks. The conservation of the mass flux, momentum flux, and energy flux are given by (9). The first two conditions imply the following relations between the fields indexed l (left) or r (right) on each side of the jump.

$$h_l v_l = h_r v_r \equiv j, \quad h_l v_l^2 + \frac{gh_l^2}{2} = h_r v_r^2 + \frac{gh_r^2}{2}, \quad (15)$$

where we introduced the (continuous) mass flux j . From these we deduce the velocities $v_{l,r}$:

$$v_l^2 = \frac{g}{2} h_r \left(1 + \frac{h_r}{h_l} \right), \quad v_r^2 = \frac{g}{2} h_l \left(1 + \frac{h_l}{h_r} \right). \quad (16)$$

To gain further insight consider the energy flux across the hydraulic jump. From the original equations (13) this should be conserved; however (as we discussed above), discontinuities are in general not physical,

indicating that the model should be completed by some dissipation process. Without considering the details of this, we just write that energy per unit time (power) is being taken out of the system at the jump. Integrating as above, the energy conservation equation (8), from $-\varepsilon$ to ε and passing to the limit, gives the power dissipation at the jump,

$$w_{lr} \equiv \lim_{\varepsilon \rightarrow 0} \int_{-\varepsilon}^{\varepsilon} e_t \, dx = -[v^3 h + 2gh^2 v]_{-}^{+}. \quad (17)$$

Using (16) we obtain the final result for the power dissipation at the jump,

$$w_{lr} = jg \frac{(h_l - h_r)^3}{2h_l h_r}. \quad (18)$$

Assuming that energy is absorbed at the jump so $w_{lr} < 0$, we get from (18) $h_l < h_r$, and from (16)

$$v_l^2 = gh_l \frac{h_r h_l + h_l}{h_l} > gh_l$$

so that $v_l > c_l$, the local wave speed while $v_r < c_r$. These inequalities indicate the stability of the hydraulic jump.

Numerical Problems and Applications

As seen above, jump conditions come from conservation laws so an accurate numerical scheme should satisfy the conservation laws. Because the jump conditions are flux conditions, it is natural to use methods that involve integrating the operator over the spatial domain to satisfy them. One way to do this is the so-called finite volume approach, where the equation is integrated over reference volumes yielding naturally the flux conditions. Another approach is to use finite element methods, where the solution is decomposed on a basis of trial functions. The relation that gives the coefficients is obtained by integrating the equation over the whole domain.

For shock waves it is essential to have numerical schemes that do not artificially smooth the shock but respect the jump conditions. Here, special staggered finite difference schemes have been suggested by Lax, Wendroff, and Godunov.

As a final application, we present the case of a wave guide whose section changes abruptly at some point. This occurs in neurons for which varicosities are known to block the propagation of nerve impulses (Scott, 2003). To simplify the discussion, let us consider the following sine-Gordon nonlinear wave equation

$$\phi_{tt} - \phi_{xx} - \phi_{yy} + \sin(\phi) = 0, \quad (19)$$

propagating in a two-dimensional T-shaped domain as shown in Figure 2 and assuming a zero normal gradient on the boundary. This describes the electrodynamics of a Josephson junction superconducting device obtained

Figure 2. A T-shaped Josephson junction. The kink solution (21) is shown in the left region as contour lines. Kink propagation is easy from right to left but is inhibited in the other direction.

by inserting a small oxide layer between two metallic plates (Scott, 2003).

First note that the total energy of the system

$$E = \int dx \, dy \, \frac{1}{2} [\phi_t^2 + \phi_x^2 + \phi_y^2 + 2(1 - \cos(\phi))] \quad (20)$$

is a constant in time. This can be seen by multiplying (19) by ϕ_t and integrating over the domain using the boundary conditions. Consider the propagation of a front (kink)

$$\phi(x, t) = 4 \arctan \left(\exp \left(\frac{x - vt}{\sqrt{1 - v^2}} \right) \right) \quad (21)$$

which is an exact solution of the one-dimensional sine-Gordon equation for which ϕ is independent of y . Inserting (21) into (20) and calculating the integrals, it can be shown that the energy is

$$E_k = 8 \frac{w}{1 - v^2}, \quad (22)$$

where w is the width in the y direction of the domain.

Let us now consider the propagation of such a front in the domain and assume it starts at $t = 0$ from the right-hand side with a negative velocity so that it will encounter the discontinuity. First, notice that because of the boundary conditions, it travels unaffected in the straight section. When it hits the discontinuity, it will cross into the small section with no apparent change in shape apart from reflected waves (see Figure 2). On the contrary, if the kink is started from the left side whose section is narrow, it will get reflected by the discontinuity unless its velocity is quite large.

The explanation of these observations lies in the conservation of the energy of the system, assuming that most of this energy is in the front. For a kink to exist in a domain of lateral extension w , its energy should be greater than $E_k(v = 0) = 8w$. When the kink is started in the right domain, its energy $E/8 = w_r/(1 - v^2) > w_r > w_l$, so we expect it to cross without trouble into the smaller section. Indeed it should gain speed, and it does. On the contrary, if the kink is started in the left domain, its speed v_l must be very large (so that $w_l/(1 - v_l^2) > w_r$ where $8w_r$ is the energy of a static kink in the region on the right) in order to cross into the

region on the right. This provides a means to realize a rectifying gate, through which signals pass in only one direction.

JUPITER'S GREAT RED SPOT

Jupiter's Great Red Spot is a large swirling cloud mass of reddish-brown appearance (see figure in color plate section). Situated in Jupiter's southern hemisphere, it straddles the south tropical zone and, to the north of this, the south equatorial belt. The Great Red Spot (GRS) is roughly elliptical in shape, with the semi-major axis zonally aligned (east-west) and with dimensions approximately 22,000 km (twice the diameter of the Earth) by 11,000 km. The atmospheric motions associated with the GRS are visible in the cloud layer near the tropopause. It is generally agreed to be a vortex (Mitchell et al., 1981); and Smith et al. (1979a) give an estimate of the vorticity. This vortex is anticyclonic (rotating in the opposite sense to that induced by the planetary rotation), that is, anticlockwise, but with a weakly counter-rotating, or possibly quiescent inner region. The GRS is at high pressure and low temperature relative to its surroundings. A striking feature associated with the GRS is the turbulent oscillating cloud system to the northwest.

In 1664, Robert Hooke observed a small dark spot in one of the southern belts of Jupiter, reported in Hooke (1665). This is considered by some contemporary authors to be an early manifestation of the GRS (see also Rogers, 1995). By observation of this feature, Hooke was able to make a good estimate of Jupiter's rate of rotation. Many further observations of this and other features of Jupiter were made by Hooke and by Giovanni Cassini over the next five years (e.g., Cassini, 1672), and intermittently by others over the

next 50 years (see Denning, 1899). However, it was not until 1831 that Samuel H. Schwabe identified what can be clearly recognized as a feature called the Hollow, in his drawing reproduced in Rogers (1995). As the Hollow is clearly apparent above the GRS in contemporary observations, this is taken to imply the presence of the GRS. Continuous observations began in 1872 (Peek, 1958) and from these it appears that the GRS was considerably larger in the late 1800s than it is now (Beebe & Youngblood, 1979; Rogers, 1995). Very much more detailed observations became available once space probes reached Jupiter; first was Pioneer 10 in 1973, then Pioneer 11 in 1974, Voyagers 1 and 2 in 1979, Galileo in 1996, and then most recently Cassini from October 1, 2000 through until March 22, 2001. The Voyager and Galileo missions (Smith et al., 1979a, b; Vasavada et al., 1998) provided very high resolution still images, while Cassini (Porco et al., 2003) gave more dynamic information. From 1994, after corrections were made to faulty optics by the Endeavour crew, the Hubble telescope has been providing good images of Jupiter and the GRS. These, along with the Cassini sequences, clearly show vortex interactions between the GRS and smaller, intermittent vortices, thus allowing a much better understanding of the underlying dynamical processes (Morales-Juberías et al., 2002).

Attempts have been made since 1961 to model the GRS and to understand the processes giving rise to the motions observed, beginning with Hide (1961), who suggested that the GRS was the visible manifestation of a Taylor column. The quantity of relevance to these calculations is the potential vorticity q . As the atmosphere of Jupiter is stably stratified and there are significant rotational effects at the scale of the GRS, the most commonly used model is the quasi-geostrophic approximation (a simplification of the complete atmospheric dynamic equations, giving a balance of horizontal pressure gradient forces and horizontal Coriolis forces due to Jupiter's rotation). Here q is defined as

$$q = f + \nabla^2 \psi + \frac{1}{\rho_0} \frac{\partial}{\partial z} \left(\rho_0 \frac{f_0^2}{N^2} \frac{\partial \psi}{\partial z} \right), \quad (1)$$

where $\psi(x, y, z, t)$ is the stream function for the flow and (x, y, z) are local cartesian coordinates, with x and y being the zonal and meridional directions, respectively, and z being a measure of the depth. The basic state density profile is $\rho_0(z)$ and the effects of Jupiter's rotation are introduced by the beta-plane approximation, the assumption that we can treat part of Jupiter as a plane, over which the Coriolis parameter f varies linearly: $f = f_0 + \beta y$, where f_0 is the reference value at the latitude of the GRS and β is the ambient potential vorticity gradient. The buoyancy frequency $N(z)$, the frequency with which a parcel of fluid

displaced from equilibrium will oscillate, is determined by the vertical temperature variation. The potential vorticity is materially conserved, according to

$$\frac{\partial q}{\partial t} + \mathbf{v} \cdot \nabla q = 0, \quad (2)$$

where the horizontal velocity $\mathbf{v} = (-\partial\psi/\partial y, \partial\psi/\partial x)$.

Many researchers have modeled the vortical motions associated with the GRS by assuming a thin upper layer of constant density (of order 100 km; Dowling & Ingersoll, 1989) above a much deeper lower layer of slightly higher density in which there is a uniform steady zonal flow, for example, Ingersoll and Cuong (1981), Marcus (1988), and Marcus et al. (1990). The surface of the upper layer is above the visible cloud level. These models assume barotropic motions, that is, uniform in depth with no horizontal component of vorticity, in the upper layer where isolated vortices are assumed to be generated by mechanisms such as zonal shear flow instability. Merger of vortices can lead to the formation of larger vortices, and the relevant issues are then the stability and lifetime of isolated vortices such as the GRS in the observed zonal shear. A statistical mechanics approach to such equilibria is provided in Michel and Robert (1994).

There have also been discussions on the role of vertical density stratification, allowing baroclinic instability, but generally limited to the quasi-geostrophic case of (1) and (2). For example, Achterberg and Ingersoll (1994) studied the barotropic and the first two baroclinic modes, and Cho et al. (2001) used as many as 60 vertical modes. The high horizontal resolution used in Cho et al. (2001) allowed the authors to generate features such as the counter-rotating core (Vasavada et al., 1998, Figure 7, reporting Galileo data and similar Voyager data), but as in all other studies to date, the turbulent cloud system to the northwest of the spot does not appear.

A deficiency of the quasigeostrophic model is that vortices with radius significantly greater than the Rossby radius of deformation, L_R , tend to decay by radiation of Rossby waves in the absence of any external forcing. (L_R is a measure of the scale at which Coriolis forces become significant.) This would imply a lifetime for the GRS much shorter than the observed period, which is certainly greater than 150 years. In addition, the quasigeostrophic equations have the disadvantage that neither anticyclonic nor cyclonic vortices are preferentially created or destroyed, whereas observations show that the GRS is anticyclonic, as are 90% of the other (typically much smaller) vortices observed on Jupiter (Mac Low & Ingersoll, 1986).

For two-layer models, the zonal flows in the bottom layer can be incorporated in a reduced gravity single-layer shallow water model with meridionally varying topography and a free surface, which is taken to be above the visible cloud layer (Dowling

& Ingersoll, 1989). There are various levels of approximation to the shallow-water equations beyond the quasi-geostrophic approximation. The intermediate geostrophic (IG) approximation (Williams & Yamagata, 1984; Nezlin & Sutyrin, 1994) arises when there is significant nonlinearity giving rise to finite free-surface distortion, as is to be expected for vortices with a scale much greater than the Rossby radius, such as the GRS. A more complete discussion of the asymptotic treatment of the nonlinear terms, along with higher-order approximations, is given in Stegner and Zeitlin (1996).

An alternative approach to understanding the GRS as a solitary wave was first introduced by Maxworthy and Redekopp (1976a,b) and Redekopp (1977). They considered the quasigeostrophic equations (1) and (2) and were able to find elementary soliton solutions in the limit of small amplitude disturbance, which obeyed either the Korteweg-de Vries equation (KdV) or the modified KdV equation. These balance zonal shear and dispersion to give isolated disturbances that could be regarded as vortices. However, as noted by several authors (e.g., Ingersoll & Cuong, 1981), these soliton solutions of the KdV equation pass through one another unchanged in form (elastic collisions). This is contrary to the behavior of vortices generally, and more particularly the GRS, where merger with smaller vortices is observed (Morales-Juberías et al., 2002). However, Petviashvili (1980), by going beyond quasigeostrophy, was able to derive solitary axisymmetric vortex solutions, without an imposed zonal shear, for a curved shallow layer, with anticyclones living longer. Nezlin et al. (1990) refer to this anticyclonic vortex as a Rossby soliton, with weak nonlinearity balanced by Rossby wave dispersion. These solitary solutions undergo inelastic collisions and were later thought to be found experimentally in parabolic water tank experiments (Nezlin et al., 1990), although Nycander (1993) and Stegner and Zeitlin (1996) demonstrated that this weakly nonlinear balance could not in fact exist in the parabolic geometry and that stronger nonlinearity was required to explain the laboratory observations. Stegner and Zeitlin (1996) go on to show that axisymmetric soliton-like solutions of a 2-d KdV equation are found for spherical geometry, corresponding to the surface of Jupiter, using a nonlinear model. Furthermore, only an anticyclonic vortex can be supported in this case, which is in accord with the observed rotation of the GRS. However, this cannot explain the preferential formation of anticyclonic vortices smaller than the Rossby radius, where the quasigeostrophic approximation remains appropriate. Finally, as explained by Stegner and Zeitlin (1996), their 2-d KdV solutions do not apply directly to the GRS as neither the elliptical shape nor the counter-rotating inner core can be accounted for.

K

KADOMTSEV–PETVIASHVILI EQUATION

The Kadomtsev–Petviashvili (KP) equation was derived by Kadomtsev & Petviashvili (1970) to examine the stability of the one-soliton solution of the Korteweg–de Vries (KdV) equation under transverse perturbations, and it is relevant for most applications in which the KdV equation arises. After rescaling of its coefficients, the equation takes the form

$$(-4u_t + 6uu_x + u_{xxx})_x + 3\sigma^2 u_{yy} = 0, \quad (1)$$

where indices denote differentiation, and σ is a constant parameter. If $\sigma^2 = -1$ (+1), the equation is referred to as the KP1 (KP2) equation. All other real values of σ^2 can be rescaled to one of these two cases. In what follows, a reference to KP (as opposed to KP1 or KP2) implies that the result in question is independent of the sign of σ^2 .

Depending on the physical context, an asymptotic derivation can result in either the KP1 or the KP2 equation. In all such derivations, the equation describes the dynamics of weakly dispersive, nonlinear waves whose wavelength is long compared with its amplitude, and whose variations in the second space dimension (rescaled y) are slow compared with their variations in the main direction of propagation (rescaled x). Two examples are as follows:

- *Surface waves in shallow water:* In this case, u is a rescaled wave amplitude with a rescaled velocity. The wavelength is long compared with the depth of the water h , which is large compared with the wave amplitude. The sign of σ^2 is determined by the magnitude of the coefficient of surface tension τ . KP1 results for large surface tension $\tau/(gh^2) > 1/3$ (thin films); otherwise, KP2 results. Here g is the acceleration of gravity. For most applications in shallow water, surface tension plays a sufficiently unimportant role, and KP2 is the relevant equation (Ablowitz &, 1979, See **Water waves**).
- *Magneto-elastic waves in antiferromagnetic materials:* Here u is a rescaled strain tensor with a

rescaled velocity. The sign of σ^2 is determined by the difference between the linear velocities of the magnons and phonons, and the strength and direction of the external magnetic field (Turitsyn & Fal'kovich, 1986).

The KP equation has different classes of soliton solutions. The first class is a generalization of the solitons of the KdV equation. These solutions decay exponentially as $x, y \rightarrow \pm \infty$, in all but a finite number of directions along which they approach a constant value. For this reason these solutions are referred to as line solitons. By appropriately choosing their parameters, the direction of propagation of each line soliton can be chosen to be anything but the y -direction. In the simplest case, the solitons all propagate in the x -direction, adding a second dimension to the KdV solitons. Many other scenarios are possible. Two line solitons can interact with different types of interaction regions to produce two line solitons, but two line solitons can also merge to produce a single line soliton. Alternatively, a single line soliton can disintegrate into two line solitons. The production or annihilation of a line soliton is sometimes referred to as soliton resonance. Although both KP1 and KP2 have line soliton solutions, soliton resonance occurs only for the KP2 equation. Line soliton solutions of the KP2 equation are stable, whereas line soliton solutions of the KP1 equation are unstable. More possibilities exist when more than two line solitons are involved. Two distinct line soliton interactions are illustrated in Figure 1.

Another class of soliton solutions exists for only the KP1 equation and decays algebraically in all directions as $\sqrt{x^2 + y^2} \rightarrow \infty$. These soliton solutions are referred to as lumps and are unstable. Individual lumps in multi-lump solutions do interact with each other but leave no trace of this interaction. A lump soliton is shown in Figure 2 (Ablowitz & Segur, 1981).

Another important class of solutions of the KP equation generalizes the exact periodic and quasi-periodic solutions of the KdV equation. A (quasi-) periodic solution with g phases is expressed in terms of

Figure 1. Two types of spatial ($t = 0$) line soliton interactions for the KP2 equation: (a) Two identical line solitons with an interaction that does not change their characteristics; (b) Two line solitons merge to produce one line soliton.

Figure 2. A lump soliton ($t = 0$) solution of the KP1 equation.

the Riemann theta function $\theta(z|\mathbf{B})$ by

$$u(x, y, t) = c + 2 \frac{\partial^2}{\partial x^2} \ln \theta(\mathbf{k}x + \mathbf{l}y + \boldsymbol{\omega}t + \boldsymbol{\phi}|\mathbf{B}). \quad (2)$$

Here, c is a constant, and $\mathbf{k}$, $\mathbf{l}$, $\boldsymbol{\omega}$, and $\boldsymbol{\phi}$ are g -dimensional vectors that are interpreted as wave vectors ($\mathbf{k}$, $\mathbf{l}$), frequencies ($\boldsymbol{\omega}$), and phases ($\boldsymbol{\phi}$). These parameters and the $g \times g$ Riemann matrix $\mathbf{B}$ are determined by a genus g compact connected Riemann surface and a set of g points on it.

For $g = 1$, solution (2) generalizes the cnoidal-wave solution of the KdV equation to two spatial dimensions. For $g = 2$, the solution is still periodic in space. Its basic period cell is a hexagon, which tiles the (x, y) -plane. These solutions translate along a direction in the (x, y) -plane. For $g \geq 3$, solution (2) is typically no longer periodic or translating in time. For some values of their parameters, these (quasi-)periodic solutions can be interpreted as infinite nonlinear superpositions of line solitons. Solutions with $g \leq 2$ have been compared with experiments in shallow water, with agreement being more than satisfactory (Hammack et al., 1995). A two-phase solution of the KP2 equation is shown in Figure 3. A good review of the finite-phase solutions of the KP equation is given by Dubrovin (1981).

Figure 3. A two-phase periodic solution of the KP2 equation.

Unlike for the KdV equation, where only a restricted class of Riemann surfaces arises, any compact connected Riemann surface gives rise to a set of solutions of the KP equation. The reverse statement is also true: if (2) is a solution of the KP equation, then matrix $\mathbf{B}$ is the normalized period matrix of a genus g Riemann surface. This statement is due to Novikov. It provides a solution to the century-old Schottky problem, and its proof is by Shiota (1986).

The KP equation is the compatibility condition $\Psi_{yt} = \Psi_{ty}$ of the two linear equations

$$\sigma \Psi_y = \Psi_{xx} + u \Psi,$$

$$\Psi_t = \Psi_{xxx} + \frac{3}{2} u \Psi_x + \frac{3}{4} (u_x + w) \Psi, \quad (3)$$

with $w_x = \sigma u_y$. These equations constitute the Lax pair of the KP equation. Using the inverse scattering method, it is the starting point for the solution of the initial-value problem for the KP equation on the whole (x, y) -plane with initial conditions that decay at infinity. The inclusion of line solitons is also possible (Ablowitz & Clarkson, 1991). Although the initial-value problem with periodic boundary conditions for KP2 was solved by Krichever (1989), this approach was unable to solve the same problem for the KP1 equation. In this context, solutions (2) are referred to as finite-gap solutions, as they give rise to operators (3) with spectra that have a finite number of forbidden gaps in them.

More details and different aspects of the theory of the KP equation are found in Ablowitz & Clarkson (1991), Ablowitz & Segur (1981), Dubrovin (1981), Krichever (1989), Shiota (1986), and references therein.

KELVIN–HELMHOLTZ INSTABILITY

The Kelvin–Helmholtz (KH) instability was originally investigated by Lord Kelvin (William Thomson) and Hermann von Helmholtz (Kelvin, 1871; Helmholtz, 1868; Chandrasekhar, 1981; Drazin & Reid, 1981; Gerwin, 1968) in the context of wind flowing over water. Their main motivation was to understand how wind ruffles the ocean surface to produce the ripples, eddies, and whitecaps that we see on our trips to the beach.

The KH instability has subsequently been observed in a variety of space, astrophysical, and geophysical settings involving sheared fluid and plasma flows. In addition to the original situations relating to ocean waves, relevant configurations include the interface between the solar wind and the upper magnetosphere, coronal streamers moving through the solar wind, the structure of the tails of comets, and the boundaries of the jets propagating from the core of extragalactic double radio sources into their lobes. Another interesting application of KH instability in this age of unexplained air disasters is the phenomenon known as clear air turbulence, where an aircraft flying through a clear sky is suddenly buffeted (*See Clear air turbulence*).

With an initial or equilibrium configuration consisting of two superposed incompressible and inviscid fluids streaming in the horizontal or z -direction at differential speeds U_1 and U_2 (see Figure 1), consider how disturbances to this configuration evolve in time. Because the velocity differential occurs at different heights (or the transition in the speed from U_1 to U_2 occurs over some finite range of x), the equilibrium configuration

Figure 1. The basic configuration for shear flow across a vortex sheet.

has finite geometrical extent in the x -direction. Note that the inviscid assumption, which holds well for air and water as well as for very low-density interstellar media, allows an arbitrary profile for the velocity transition from U_1 to U_2 with the x transition length chosen to fit experiments. By contrast, the equilibrium is of semi-infinite extent in the horizontal or z -direction, and of infinite extent in y . Thus, one may represent field variables as Fourier series in the directions y and z which are of infinite extent, thereby assuming elementary disturbances of the form

$$\chi \sim f(x) \exp[i(k_y y + k_z z - \omega t)] \quad (1)$$

for all variables χ . Here, k_y and k_z are the y and z wave numbers, and ω is the angular frequency. (Note also that only a single mode among the infinite number needed to expand the variable χ as a Fourier series has been displayed in this equation.)

Substitution of Equation (1) into the equations governing the fluid flow yields a functional relationship between the angular frequency and the wave number called the dispersion relation, which provides key information regarding the propagation of the mode of Equation (1). Importantly, there are situations where the dispersion relation yields complex angular frequencies, that is,

$$\omega = \omega_r + i\omega_i. \quad (2)$$

The temporal exponential growth or decay of the mode is then controlled by ω_i (called the growth rate), while its oscillation frequency is governed by ω_r . Important for us are the unstable cases where $\omega_i > 0$ so the disturbance grows in time. In such cases, χ does not settle back to the original equilibrium, and one must consider the consequences of this growth.

A driving parameter for KH instability is the differential flow speed (velocity shear) of the two layers of fluid, and it suffices to consider one Fourier mode while investigating the stability of a system. The key concept here is that the wave number of the normal mode is left arbitrary, and the system is unstable if $\omega_i > 0$ for any wave number. In general, the system is stable for some range of the driving parameter and becomes unstable beyond a critical value

of the parameter. The wave number that first becomes unstable as this critical parameter value is reached selects the most unstable mode, which usually guides the further development of the instability.

Let us apply these concepts by substituting Equation (1) into the dynamical equations governing the flow. In the simplest form of the analysis (linear theory), one neglects all nonlinear terms (where any of the field variables are raised to higher than linear powers, or where there are products of different field variables) to obtain a dispersion relation. This relation satisfies boundary conditions at the discontinuity corresponding to the continuity of the normal (perpendicular) speed, the normal magnetic field (if any), and the normal total (fluid plus electromagnetic) stress. The resulting dispersion relation in the incompressible fluid case is given by (Chandrasekhar, 1981)

$$\omega = k_z(\alpha_1 U_1 + \alpha_2 U_2) \pm \left[gk \left\{ (\alpha_1 - \alpha_2) + \frac{k^2 T}{g(\rho_1 + \rho_2)} \right\} - k_z^2 \alpha_1 \alpha_2 (U_1 - U_2)^2 \right]^{1/2}.$$

Here, g is the acceleration of gravity, T is the coefficient of surface tension, and

$$\alpha_1 = \frac{\rho_1}{\rho_1 + \rho_2}, \quad \alpha_2 = \frac{\rho_2}{\rho_1 + \rho_2}, \quad (3)$$

where ρ_i is the density of the i -th fluid. Analysis of Equation (3) reveals instability ($\omega_i > 0$) for (Kelvin, 1871; Chandrasekhar, 1981)

$$(U_1 - U_2)^2 > \frac{2}{\alpha_1 \alpha_2} \sqrt{\frac{Tg(\alpha_1 - \alpha_2)}{\rho_1 + \rho_2}}. \quad (4)$$

For air over sea water, this implies instability at $U_1 - U_2 > 650$ cm/s (14.8 mph) manifested as surface waves of about 1.71 cm wavelength.

The sea, however, is stirred by winds of smaller speeds than this, and a variety of effects have been advanced to explain this discrepancy. These include continuous velocity variation rather than an abrupt jump at the surface, continuously varying density profiles, rotational effects (due to the Earth's rotation), as well as Lord Kelvin's original suggestion—the effects of viscosity (Chandrasekhar, 1981; Drazin & Reid, 1981).

In addition, compressibility and various electromagnetic fields (Choudhury, 1986; Choudhury & Lovelace, 1984; Miura, 1990; Miura & Pritchett, 1982) become important in magnetospheric, geophysical, and astrophysical settings where there are high-speed shear flows and large fields. An important effect of compressibility is to introduce a second unstable traveling-wave mode

with nonzero ω_r , in addition to the standing-wave unstable mode (with zero ω_r) which exists in the incompressible limit.

There have been numerous computer simulation studies of KH instability in a variety of settings (Miura, 1995; Normal et al., 1982). The effect of anisotropic pressure has also been comprehensively considered (Brown & Choudhury, 2000).

Finally, it is important to consider nonlinear effects on the instability since the temporal growth of the linear fields in Equation (1) will eventually reach amplitudes large enough so that product terms can no longer be ignored. From physical considerations, one may also argue that exponential linear growth as predicted by Equation (1) for $\omega_i > 0$ is not tenable indefinitely because the energy is proportional to the square of the field amplitude and this energy is limited. Clearly, nonlinear effects must come into play and limit the linear growth (Debnath & Choudhury, 1997; Drazin & Reid, 1981; Weissman, 1979). Such nonlinear evolution studies reveal a variety of interesting dynamical behaviors from quasi-periodicity and chaos at one extreme (Choudhury & Brown, 2001) to self-organization and coherent structures at the other (Miura, 1999). A formulation of the problem in terms of noncanonical Hamiltonians for the fluid dynamical equations (Benjamin & Bridges, 1997) enables one to follow instability evolution well into its late stages where the interface has become appreciably folded.

KERR EFFECT

Discovered by John Kerr in 1875, the electro-optical effect opened new trends in the world of optics. This effect refers to the modifications that a light beam undergoes in amplitude, phase, or direction when it propagates in an optical material that responds to an external electric field. An example is the modulation of optical radiation in crystals in which two possible linearly polarized modes exist with unique directions of polarization and corresponding indices of refraction. For crystals with no inversion symmetry, $(n^2)_{ij}$ denotes the squared ray index along the directions

$(i, j) = 1, 2, 3$, such as $x = 1, y = 2, z = 3$. The linear change in the coefficients $(1/n^2)_{ij}$ due to an applied low-frequency electric field $\mathbf{E}(E_x, E_y, E_z)$ is then defined by

$$\Delta \left(\frac{1}{n^2} \right)_{ij} = \sum_k r_{ijk} E_k \quad (k = 1, 2, 3), \quad (1)$$

where the 6×3 matrix with elements r_{ijk} is called the electro-optical tensor. Current applications of this property are electro-optic retardation, amplitude or phase modulation, and beam deflection (Yariv, 1975).

Optical nonlinearities result from an analogous effect arising when the low-frequency electric field applied is replaced by a second optical frequency. Let us consider the electric field of an optical beam along the j -direction with frequency ω_1 : $E_j^{(\omega_1)}(t) = \text{Re}(A_j^{(\omega_1)} e^{-i\omega_1 t})$ while a second field at ω_2 is $E_k^{(\omega_2)}(t) = \text{Re}(A_k^{(\omega_2)} e^{-i\omega_2 t})$. If the medium is nonlinear, these fields generate polarizations at frequencies $\omega_3 = n\omega_1 + m\omega_2$, where n and m are any integers. The susceptibility tensor $d_{ijk} = -\epsilon_i \epsilon_j r_{ijk} / 2\epsilon_0$ then enters the polarization vector as $P_i^{(\omega_3)} = \sum_j \sum_k d_{ijk} A_j^{(\omega_1)} A_k^{(\omega_2)}$, where ϵ_i and ϵ_j are the dielectric constants along i and j at ω_1 , and ϵ_0 is the vacuum permittivity.

A single optical beam is able to induce nonlinear effects. The origin of the nonlinear response is then related to anharmonic motions of bound electrons under the influence of a primary optical field. As a result, the induced polarization $\mathbf{P}$ created from the electric dipoles is not linear in the electric field $\mathbf{E}$, but it satisfies the more general relation

$$\begin{aligned} \mathbf{P} &= \mathbf{P}_L + \mathbf{P}_{NL} \\ &= \epsilon_0 \{ \chi^{(1)} \cdot \mathbf{E} + \chi^{(2)} : \mathbf{E}\mathbf{E} \\ &\quad + \chi^{(3)} : \mathbf{E}\mathbf{E}\mathbf{E} + \dots \}, \end{aligned} \quad (2)$$

where $\chi^{(n)}$ ($n = 1, 2, \dots$) is the n th-order susceptibility tensor of rank $n + 1$. The linear susceptibility $\chi^{(1)}$ represents the dominant, linear contribution to $\mathbf{P}$,

$$\mathbf{P}_L = \epsilon_0 \int_{-\infty}^{+\infty} \chi^{(1)}(t - t') \cdot \mathbf{E}(\mathbf{r}, t') dt', \quad (3)$$

including the linear refractive index n_0 and related attenuation coefficient. $\chi^{(2)}$ is the second-order susceptibility responsible, for example, for second-harmonic generation in crystals with a lack of inversion symmetry. For centro-symmetric media such as optical fibers, silica samples, and gases, this contribution is zero and the first nonlinearities are provided by the third-order susceptibility $\chi^{(3)}$ through

$$\begin{aligned} \mathbf{P}_{NL} &= \epsilon_0 \int \int \int_{-\infty}^{+\infty} \chi^{(3)}(t - t_1, t - t_2, t - t_3) \\ &\quad : \mathbf{E}(\mathbf{r}, t_1) \mathbf{E}(\mathbf{r}, t_2) \mathbf{E}(\mathbf{r}, t_3) dt_1 dt_2 dt_3. \end{aligned} \quad (4)$$

This causes an intensity dependence in the total refractive index of the form

$$n = n_0 + n_2 |E|^2 \quad (5)$$

with nonlinear coefficient $n_2 = 3\chi_{xxxx}^{(3)}/8n_0$ for a linearly polarized electric field involving a single $\chi^{(3)}$ component of four-rank tensor. This intensity dependence induced in the refractive index through $\chi^{(3)}$ contributions is called the Kerr effect.

The Kerr effect affects the evolution of the electric field E , which is governed by Maxwell's equations. Straightforward combination of the latter, after eliminating the magnetic and electric flux density ($D = \epsilon_0 E + P$), provides the wave equation

$$\nabla \times \nabla \times E + \frac{1}{c^2} \partial_t^2 E = -\mu_0 \partial_t^2 P, \quad (6)$$

where $\mu_0 \epsilon_0 = 1/c^2$ and c is the speed of light in vacuum. For treating Equation (6) conveniently, certain assumptions can be made, among which are the following:

- $|P_{NL}|$ is a small perturbation to the total induced polarization.
- Optical losses are weak, so that the imaginary part of the frequency-dependent dielectric constant $\epsilon(\omega)$ is negligible, that is, $\epsilon(\omega) = 1 + \tilde{\chi}^{(1)}(\omega) \simeq n^2(\omega)$.
- $\nabla \cdot D \simeq \epsilon \nabla \cdot E = 0$, and thus $\nabla \times \nabla \times E = \nabla \cdot (\nabla E) - \nabla^2 E \simeq -\nabla^2 E$.
- The polarization state is preserved, so that a scalar approach is valid.
- The optical field is quasi-monochromatic; that is, its spectrum centered at $\omega_0 = 2\pi c/\lambda_0$ for the wavelength λ_0 has a spectral width $\Delta\omega = \omega - \omega_0$ satisfying $\Delta\omega/\omega_0 \ll 1$.

It is then useful to separate out the rapidly varying part of the electric field, like $E(r, t, z) = \hat{x}A(r, t, z)e^{-i(\omega_0 t - k_0 z)}$ for a wavefield propagating along the z axis with wave number $k_0 = k(\omega_0) = n_0\omega_0/c$. As a result, the complex envelope A is described by the nonlinear Schrödinger (NLS) model (Brabec & Krausz, 1997)

$$i\partial_\xi A + \frac{1}{2k_0} T^{-1} \nabla_\perp^2 A + \hat{D}A + \frac{\omega_0 n_2}{c} T(|A|^2 A) = 0, \quad (7)$$

after passing over to the frame moving with the group-velocity, by means of the new variables $\xi = z$, $\tau = t - \beta_1 z$ where $\beta_1 \equiv \partial k/\partial \omega|_{\omega_0}$. Here, the assumptions of paraxiality ($|\partial_\xi A| \ll k_0 |A|$) and slow variations in time ($|\partial_\tau A| \ll \omega_0 |A|$) have been made. The transverse Laplacian $\nabla_\perp^2 = \partial_x^2 + \partial_y^2$ accounts for wave diffraction in the x - y plane [$r = (x, y)$]. $\hat{D} \equiv \sum_{m=2}^{+\infty} \frac{1}{m!} (\partial^m k/\partial \omega^m|_{\omega_0}) (i\partial_\tau)^m$ is the dispersion operator, where only the leading-order contribution ($m=2$) is considered below, which corresponds to group-velocity dispersion (GVD) with coefficient

$\beta_2 \equiv \partial^2 k/\partial \omega^2|_{\omega_0}$. The operator $T = 1 + (i/\omega_0)\partial_\tau$ originates from the cross derivatives $\partial_{\xi\tau}^2$ retained in the derivation of Equation (7), and it reduces to unity, whenever $\Delta\omega/\omega_0 \ll 1$ holds. For $n_2 > 0$, the principal physical processes caused by the Kerr effect can be listed as follows:

- The Kerr effect creates spectral broadening through self-phase modulation (SPM). Solving for $i\partial_\xi A = -\omega_0 n_2 |A|^2 A/c$ indeed yields the exact solution $A = A_0 e^{i\omega_0 n_2 |A_0|^2 \xi/c}$ with $A_0 = A(\xi=0)$, which describes a self-induced phase shift experienced by the optical field during its propagation. This intensity-dependent phase shift refers to SPM, which is responsible for the spectral broadening of short pulses by virtue of the relation $\Delta\omega/\omega_0 = -\partial_\tau \arg(A)/\omega_0$. The pulse shape does not change in time, but the frequency spectrum is expanded by the nonlinearity.
- In optical fibers for which diffractive effects are negligible, pulses mainly undergo GVD and Equation (7) reduces to the standard cubic NLS equation in the limit $T \rightarrow 1$. With $\beta_2 < 0$ (so-called anomalous GVD), this equation describes the balance between 1-d dispersion and nonlinearity, which gives rise to sech-shaped, "bright" temporal solitons. With $\beta_2 > 0$ (normal GVD), "dark" solitons appear as localized dips against a uniform background. Both types of solitons have been detected experimentally (Agrawal, 1989). Solitons in dispersion-managed optical fibers, prepared with alternating spans of normal and anomalous GVD, have important applications in high-rated data communication systems over distances of many kilometers.
- For ultrashort pulses developing sharp temporal gradients, the operator T in front of the Kerr term in (7) induces shock dynamics: the field intensity without GVD and diffraction is governed by the continuity relation $\rho_\xi + 3n_2 \rho \rho_\tau /c = 0$ with $\rho = |A|^2$. For localized pulses with compact distribution F , ρ has the exact implicit solution $\rho = F(\tau - 3n_2 \xi \rho/c)$, which gives rise to a singular shock profile with $|A_\tau| \rightarrow +\infty$ in the trail ($\tau > 0$) of the pulse. This effect is usually called self-steepening (Anderson & Lisak, 1983). A comparable formation of a trailing shock edge, called space-time focusing, follows from the operator T^{-1} acting on diffraction (Rothenberg, 1992).
- For beams with no temporal dispersion ($T=1$, GVD=0), Equation (7) describes the self-focusing of optical wave packets (Marburger, 1975). Self-focusing arises as a shrinking of the beam in the diffraction plane, which is achieved by a transverse collapse when no saturation of the Kerr nonlinearity takes place. This process develops when the input power $P_{in} = \int |A|^2 dr$ exceeds the critical value $P_{cr} \simeq \lambda_0^2/2\pi n_0 n_2$. The beam waist then decreases

more and more, as the field amplitude $|A|$ diverges. In media such as CS_2 liquids (Campillo et al., 1973), the optical field distribution is modulationally unstable, and self-focusing often produces filamentation, along which the background beam is broken up into small-scale cells that self-focus in turn. Their growth is, however, generally arrested by higher-order nonlinearities coming from Equation (2), which can form stable spatial solitons.

- By mixing GVD and spatial diffraction when $T \simeq 1$, the Kerr nonlinearity causes defocusing in time for $\beta_2 > 0$ and temporal compression for $\beta_2 < 0$, in addition to wave focusing in the transverse direction. The interplay of these processes results in the symmetric splitting of the pulse along the time axis with normal GVD and to a 3-d spatiotemporal collapse with anomalous GVD (Bergé, 1998).
- Finally, the Kerr response of optical media favors cross-phase modulation (XPM). XPM refers to the nonlinear phase shift of an optical field induced by a copropagating beam at a different wavelength. Noting the total electric field as $E = \hat{x} E[A_1 e^{-i\omega_1 t} + A_2 e^{-i\omega_2 t}]$ for two components with different frequencies ω_1 and ω_2 , the phase shift for the field at ω_1 over a length L is given by $\phi_{\text{NL}} = n_2 k_0 L (|A_1|^2 + 2|A_2|^2)$. The last term refers to XPM, from which spectral broadening is larger than that for one wave alone. Coupling of several wave components belongs to the category of parametric processes, among which are the third-harmonic generation, four-wave mixing and parametric amplification (Shen, 1984; Agrawal, 1989).

KICKED ROTOR

The properties of a classical and/or quantum kicked rotor can be understood by examining how nonlinearities influence the dynamics of conservative dynamical systems. The story begins with the French mathematician Henri Poincaré and his famous study of planetary motion (Poincaré, 1892). Unlike the integrable two-body problem, a third body added to the system experiences nonperiodic motion (See ***N-body problem***). Indeed, the trajectory of a light mass moving under the influence of the gravity of two heavy masses is very complex, and we know that such an orbit is fractal. This is one end of the spectrum of dynamical possibilities; on the other end are the integrable Hamiltonian equations of the Kolmogorov–Arnol’d–Moser (KAM) theory.

Thus, in one limit we have the integrable Hamiltonians that are the subject of the KAM theory, and in another we have non-integrable Hamiltonians, an example of which is the three-body problem of Poincaré. So how do we get from one side to the other using a perturbed Hamiltonian? In the unperturbed system, the various degrees of freedom are uncoupled, given by the action-angle variables, and the motion unfolds on KAM tori. Small perturbations leave the motion essentially unchanged, but even then nonlinear resonances are introduced in restricted regions of phase space. These nonlinear resonances change the dynamics of the system and deform the tori on all scales as the strength of the perturbation increases, leading to breakup of the KAM tori and chaos.

The properties of such nonlinear resonances can be examined using maps, which in a Hamiltonian system is equivalent to using a strobe lamp to register the momentum and displacement at equally spaced time intervals. One map that approximates several physical systems is the Taylor–Chirikov or standard map (Chirikov, 1979). For the n th flash we have for this map the momentum p_n and displacement x_n ,

$$p_{n+1} = \frac{K}{2\pi} \sin(2\pi x_n), \quad x_{n+1} = x_n + p_{n+1}. \quad (1)$$

Figure 1 shows a sequence of standard map plots for increasing values of the coupling strength K . Each of the continuous curves is the result of a mapping of a single initial condition. The orbits in the vicinity of $p = 0.5$ in Figure 1a are those of a simple pendulum, which is the “harmonic oscillator” of nonlinear dynamics. As the size of K is increased, Figure 1b shows that the nonlinear resonances generate more and more structure in the phase space as well as deforming the already existing KAM tori. The tori break up into sprays of

points, beginning in the vicinity of the nonlinear resonances, whose exact locations are sensitively dependent on initial conditions. This is chaos, and as K is further increased, the chaos spreads throughout the phase space among the islands of stability, as in Figure 1c. There is no way to predict the motion of the trajectory in the chaotic sea. Further increases in the coupling parameter result in more tori disintegrating until the phase space appears to be completely dominated by chaos and all but the most stable of the KAM tori have disappeared, as in Figure 1d.

The standard map is also called a kicked rotor because it describes the strob plot of the phase space trajectories for a rotor kicked every T units of time with a strength that depends on the angular position of the rotor. The Hamiltonian for the classical kicked rotor (CKR) can be written as (Chirikov, 1979; Reichl, 1992)

$$H = \frac{J^2}{2I} + K \cos \theta \sum_{k=-\infty}^{k=\infty} \delta(t - nT), \quad (2)$$

Figure 1. The phase space orbits for the kicked rotor are depicted for four values of the coupling strength: (a) $K = 0.1716354$; (b) $K = 0.4716354$; (c) $K = 1.1716354$, and (d) $K = 3.9716354$ (from Reichl, 1992).

where J is the angular momentum of the rotor, θ is its angular position, and I is the moment of inertia. Reichl (1992) reviews how to obtain the discrete map (2) by integrating the Hamiltonian equation of motion generated by (3) from one pulse to the next.

Hamiltonian (3) provides a classical description of an electron subjected to a periodically pulsed electric field. The nonlinear mechanisms are present in the motion of charged particles in accelerators and storage rings, as well as in the motion of planets and man-made celestial bodies. In the classical case, the particle dynamics in the chaotic sea are interpreted as diffusion, under which the mean-square separation of trajectories increases linearly in time with a diffusion coefficient given by $2D \approx K^2$. Thus, for the coupling strength (K) sufficiently large, the dynamical system behaves like simple Brownian motion. This has led a number of investigators to conjecture that chaos provides the dynamical foundation of thermodynamics, rather than the usual heat bath, with an infinite number of degrees of freedom (Ford & Waters, 1963; Chirikov, 1979). For example, the fluctuation-dissipation relation has been generated using nonlinear dynamical systems (Bianucci et al., 1995).

The quantum kicked rotor (QKR) employs a quantized version of the Hamiltonian, where the angular momentum J is replaced with the operator $i\hbar \partial/\partial\theta$. The mapping is carried out using the Floquet theory on the Schrödinger equation, because the Hamiltonian is periodic in time. There is a remarkable similarity between the QKR and the one-dimensional tight-binding model of Anderson localization in solid state physics. The dynamical evolution of the QKR can be determined analytically in terms of a Floquet map, where the Floquet momentum eigenstates are exponentially localized for irrational kicks and extended for rational kicks (Reichl, 1992). It has been established that the quantum density for the momentum states is a truncated Levy distribution in direct analogy with the classical probability density as shown in Figure 2 (Stefancich et al., 1998). The peaks on either side of the classical and quantum

Figure 2. On the left is depicted the classical probability density for the dimensionless momentum of the CKR after 20 iterations of the map (2) and the solid curve is the theoretical prediction of the truncated Lévy distribution. On the right is the quantum probability density after 20 iterations for the QKR (Stefancich et al., 1998).

distributions correspond to the outward propagation of the initial states at maximum velocity. Finally, the CKR and QKR have been used to describe the experimental “quasifractal” structures resulting from a periodically kicked spin system in the semiclassically large-spin regions (Nakamura, 1993).

KIRCHHOFF'S LAWS

Introduction

Kirchhoff's laws are conservation rules for networks; given a particular network topology, they prescribe how its currents and voltages are related. This not only facilitates understanding of the behavior of a network, but also allows an analyst to write down the equations that govern its behavior. These laws were named after Gustav Robert Kirchhoff, who in 1845 published one of the first systematic treatises on the laws of circuit analysis. Kirchhoff's current law (KCL) states that the sum of all currents into any node (or single point) of the network is zero; thus the charge flowing in and out is balanced, which makes intuitive sense. In the network of Figure 1, this means that I_1 and I_4 are equal in magnitude (KCL at node A), and that the algebraic sum of I_1 , I_2 , and I_3 is zero (KCL at node B).

Kirchhoff's voltage law (KVL) states that the sum of voltages around a closed loop is zero, which is expected because traversing a loop brings one back to the starting

Figure 1. A simple electric network.

point. In Figure 1, this means that V_2 and V_3 are equal (KVL around loop D), and that the algebraic sum of V_1 , V_2 , and V_4 is zero (KVL around loop C). Signs and directions can be confusing in both cases, and it is important to note these correctly. A positive current entering a node is the same as a negative current leaving a node. Also, moving from the negative to positive voltage (potential) terminal of an element entails a potential rise, while moving in the opposite direction entails a drop. Passive network elements create voltage drops; active ones such as voltage sources can create voltage rises.

As with any such rules, there are some caveats. KCL actually specifies that current into a “cutset,” not just a node, is zero; a cutset is any part of the network that is enclosed by a closed curve, such as the dotted circle in Figure 1. Moreover, KCL does not hold if nodes (or cutsets) can store, consume, or produce charge. KVL, on the other hand, is only valid if the voltage (or potential) between two points is independent of the path one takes between the points. If energy is lost or created as it moves around a loop, KVL does not hold.

Applications to Electronic Circuits

Kirchhoff's laws find their most common use in electronics. In Figure 2, for example, KVL around the left- and right-hand loops, respectively, yields $-V + V_1 + V_2 = 0$ and $-V_2 + V_3 = 0$, and KCL written at the point where the three resistors join yields $I_1 - I_2 - I_3 = 0$. These relationships are fairly obvious in such a simple network, assuming one gets the directions and the associated signs right. KVL and KCL become important when the network topology is complex or when one wants to automate the process in a computer algorithm.

If the constitutive relations (voltage-current characteristics) of the elements in a network are known, one can rewrite either set of equations in terms of the other state variables. Resistors, for example, obey Ohm's law ($V = IR$), so the first KVL equation can be rewritten in terms of the currents: $V = I_1 R_1 + I_2 R_2$.

The governing equations for a simple resistor circuit as in Figure 2 are linear and algebraic. When the

Figure 2. A resistor network.

Figure 3. A simple oscillator circuit.

circuit includes inductors and capacitors, the equations become integro-differential, but Kirchhoff's laws work just as well, and they also handle nonlinear components easily. The circuit of Figure 3, for instance, is an example of the van der Pol oscillator. In this case, KCL simply states that the currents through all three elements are identical. KVL implies that $V_1 + V_c - V_r = 0$. The constitutive relations for the capacitor and inductor are $I_c = C \, dV_c/dt$ and $V_1 = L \, dI_i/dt$, and the resistor in this circuit is nonlinear: $V_r = -aI_r + bI_r^3$. Thus, KVL can be rewritten as

$$L \frac{dI_i}{dt} + \frac{1}{C} \int I_c dt + aI_r - bI_r^3 = 0.$$

Other Applications

These ideas generalize beyond electronic circuit analysis. Many other systems, ranging from vehicle suspensions to social groups, can be described by networks. Moreover, KVL and KCL are actually instances of a more general set of laws. In the late 1950s and early 1960s, inspired by the realization that the principles underlying KCL and Newton's third law were identical (summation of {forces, currents} at a point is zero, respectively; both are manifestations of the conservation of energy), researchers began combining multi-port methods from a number of engineering fields into a generalized engineering domain with prototypical components (Paynter, 1961). The basis of this generalized physical networks (GPN) paradigm is that the behavior of an ideal two-terminal element—the “component”—can be described by a mathematical relationship between two dependent variables: generalized flow and generalized effort, where flow $\times$ effort = power. This pair of variables

Figure 4. (a) An electrical circuit that is mathematically equivalent to (b) a mechanical circuit.

is different in each domain: (flow, effort) is (current, voltage) in an electrical domain and (force, velocity) in a mechanical domain.

The GPN representation brings out similarities between components and properties in different domains. Electrical resistors ($v = i R$) and mechanical dampers or “dashpots” ($v = f B$) are analogous, as both dissipate energy. Both of the networks in Figure 4, for example, can be modeled by a series inertia-resistor-capacitor GPN. Thus network (a) is an electronic RLC circuit (like the van der Pol example of Figure 3), and network (b) is a mechanical mass-spring-damper system that has identical behavior. Similar analogies exist for generalized inertia, capacitance, flow, and effort source components for mechanical rotational, hydraulic, and thermal domains (Karnopp et al., 1990, Sanford, 1965). These correspondences and generalizations allow applications of KVL and KCL to mechanical structures (buildings, vehicle suspensions, aircraft, etc.), which can be modeled as interconnected networks of masses, springs, and dashpots. This approximation gives analytic insight into the vibrational modes of buildings (important for earthquake protection) and of aircraft (to keep engine frequencies from damaging wings).

KNOT THEORY

A simple closed curve in three-dimensional space is a knot; more precisely, if M denotes a closed orientable three-manifold, then a smooth embedding of S^1 in M is called a knot in M . A link in M is a finite collection of disjoint knots, where each knot is a component of the link. Knot theory deals with the study and application

of mathematical properties of knots and links in pure and applied sciences. As purely mathematical objects, knots are studied for the purpose of classifying three-dimensional surfaces according to the degree of topological complexity, regardless of their specific embedding and geometric properties (Figure 1). In this sense, knot theory is part of topology. In recent years, however, knot theory has embraced applications in dynamical systems, stimulated by the challenging difficulties associated with the study of physical knots (Kauffman, 1995). In this context knots and links are representatives of virtual and numerical objects (given by dynamical flows, phase space trajectories, and visiometric patterns), and are used to model tube-like physical systems, such as vortex filaments, magnetic loops, electric circuits, elastic cords, or even high-energy strings. For physical knots, topological issues and geometric and dynamical aspects are intimately related, influencing each other in a complex fashion. Virtual or numerical knots are studied in relation to the generating algorithms and the probability of forming knots, whereas the study of physical knots addresses questions relating topology and physics, as in the case of the topological quantum field theory (Atiyah, 1990) and topological fluid mechanics (Arnol'd & Khesin, 1998; Ricca, 2001).

Mathematical Aspects

Let us introduce some basic mathematical concepts (see, for example, Adams, 1994). A knot is said to be oriented in M , if it is a smooth embedding of an oriented curve. Two knots K and K' are said to be equivalent if there exists a smooth orientation-preserving automorphism $f : M \rightarrow M$ such that $f(K) = K'$; in particular, if the knot K is continuously deformed by f (preserving the curve orientation) to the knot K' , then the two knots K and K' are said to be equivalent by ambient isotopy, and the isotopy class of K is represented by its knot type. Since knot theory deals essentially with the properties of knots and links up to isotopy, the knot parametrization, as well as any other geometric information, is irrelevant. A knot diagram of K is a plane projection with crossings marked as under or over; among the infinitely many diagrams representing the same knot K , the minimal diagram is the diagram with a minimum number of crossings. According to the type of crossing, it is customary to assign to each crossing in the knot diagram the value $\varepsilon = +1$ or $\varepsilon = -1$, as shown in Figure 2: by switching one crossing in the knot diagram from positive to negative (or the other way round), we obtain a different knot type, which is identical except for this crossing. By switching all the crossings we obtain the mirror image of the original knot. If the knot is isotopic to its mirror image, then its knot type is said to be achiral, otherwise it is chiral.

Figure 1. Three examples of knot and link types: (a) the six-crossing knot 6_3 ; (b) the two-component six-crossing link 6_2^2 ; (c) the three-component seven-crossing link 7_1^3 .

Figure 2. Standard crossing notation and algebraic sign convention for oriented strands: $\varepsilon(K_-) = -1$; $\varepsilon(K_0) = 0$; $\varepsilon(K_+) = +1$.

A knot invariant is a quantity whose value does not change when it is calculated for different isotopic knots. There are many types of invariants of knots and links, but the most common are of numerical or algebraic nature. One of the most important is the genus $g(K)$ of the knot K : recall that closed orientable surfaces are classified by genus, given by the number of handles in a handle-body decomposition. The genus $g(K)$ is defined as the minimum genus over all orientable surfaces S , which span an oriented knot K , where $\partial S = K$. One of the simplest combinatorial invariants of a knot is the minimum number of crossings of a knot K in any projection, called the crossing number $c(K)$. A fundamental invariant of links is the linking number $\text{Lk}(K_1, K_2)$, that measures the topological linking between the knots K_1 and K_2 ; this invariant, discovered by Carl Friedrich Gauss in 1833, can be easily calculated by the crossing sign convention of Figure 2:

$$\text{Lk}(K_1, K_2) = \frac{1}{2} \sum_{r \in K_1 \cap K_2} \varepsilon_r, \tag{1}$$

where $\varepsilon_r = \pm 1$ and $K_1 \cap K_2$ denotes the total number of crossings (not necessarily minimal) between K_1 and K_2 . Following the pioneering work of James W. Alexander, who used a Laurent polynomial $\Delta_K(q)$ in q to compute a polynomial invariant for the knot K by using its projection on a plane, many other polynomial invariants have been introduced; most notably the Jones polynomial $V_K(t)$ in $t^{1/2}$, defined by the following set of axioms:

- (i) Let K and K' be two oriented knots (or links), which are ambient isotopic. Then

$$V_K(t) = V_{K'}(t). \tag{2}$$

(ii) If U is the unknotted loop (that is the unknot), then

$$V_U(t) = 1. \quad (3)$$

(iii) If K_+ , K_- , and K_0 are three knots (links) with diagrams that differ only as shown in the neighborhood of a single crossing site for K_+ and K_- (see Figure 2), then the polynomial satisfies the following skein relation

$$t^{-1}V_{K_+}(t) - tV_{K_-}(t) = (t^{1/2} - t^{-1/2})V_{K_0}(t). \quad (4)$$

An important property of the Jones polynomial (which is not shared by previous polynomials) is that it can distinguish between a knot and its mirror image. Later work has led to other polynomial invariants, namely, the HOMFLY and Kauffman polynomials, and to a more abstract approach to algebraic invariants (Vassiliev invariants and Lie algebras). There are also invariants of different nature: among these, we mention the fundamental group $\pi_1(S^3/K)$ of the knot complement and its hyperbolic volume $v(K)$. The classification of knots and links has led to the important study of braids: these are given by a set of n interlaced strings, with ends defined on two parallel planes, placed at some distance h apart. According to specific topological characteristics, we may consider special types of knot sub-families, such as torus knots, alternating knots, two-bridge knots, tangles, and many others (see Hoste et al., 1998).

Virtual Knots

Virtual knots arise from dynamical flows, generated by the vector field of a specific ordinary differential equation (Ghrist, 1997), in connection with phase-space dynamics and statistical mechanical models (Millett & Sumners, 1994) or, as recently done, from application of ideas from the quantum field theory with an appropriate Lagrangian. This latter approach, originated in work by E. Witten in 1989, has led to the creation of a new area, called the topological quantum field theory, that has proven to be extremely fruitful in providing new results on invariants of low-dimensional manifolds. Soliton knots are given by solutions to soliton equations for one-dimensional systems: in this context there are intriguing questions relating topological invariants, integrability, and conservation laws. Virtual knots and links are generated in visiometrics by numerical simulations: in this case, smooth knots are replaced by polygonal knots, where the number of segments (or sticks) is the result of numerical discretization. Stimulating questions address the minimum number of sticks of given length for each knot type and the generation of knots and links by minimal random walks. Other questions regard charged knots: these are knots and links charged by potentials that generate self-attraction or repulsion on the knot strands (see Figure 3). Under volume-preserving diffeomorphisms, the knot is led to relax by

Figure 3. Examples where a topological barrier prevents further relaxation under a volume-preserving diffeomorphism: (a) an electrically charged trefoil knot is maximally extended by the Coulomb repulsion forces to its minimum energy state; (b) a magnetic link attains ground state energy by the action of the Lorentz force on the magnetic volume.

minimizing the knot energy (defined by an appropriate functional), by shrinking or extending the length as far as possible, depending on the potential, to attain an ideal shape (Stasiak et al., 1998). Questions relating to topology and geometry of ideal shapes, and uniqueness of minimum energy states, pose challenging problems at the crossroads of topology, differential geometry, functional analysis, and numerical simulation.

Physical Knots

By physical knots we mean tube models, centered around the knot K , with length $L(K)$, tubular neighborhood of radius $r(K)$, and volume $V(K)$. The tube is filled by vector field lines, whose distribution gives physical properties in terms, for example, of elasticity, vorticity, or magnetic field. A wide variety of filamentary systems present in nature at very different scales can be modeled by physical knots: from DNA molecules, polymer chains, vortex filaments, to elastic cords, strings, and magnetic flux tubes. In fluid systems, the action at a microscopic level of physical processes, such as viscosity and resistivity, may imply changes in knot topology by local recombination of the knot strands (known as knot surgery) and consequential rearrangement of energy distribution. In elastic systems, the material breaking point and internal critical twist are strongly influenced by knot strength and rope length, the latter given by the ratio L/r . All these systems are free to relax their internal energy to states of equilibrium: lower bounds on equilibrium energy for given measures of topological complexity (based, for example, on crossing number information) can be expressed by relationships of the kind

$$E_{\min} \geq h(c, \Phi, V, n), \quad (5)$$

where $E_{\min}$ is the equilibrium energy and $h(\cdot)$ gives the relationship between physical quantities—such as flux Φ , number of components n , knot volume V —and topology, given here by the crossing number c .

Understanding the interplay between topology and energy localization and redistribution can be very important in many fields of science and applications.

KOLMOGOROV CASCADE

The velocity fluctuations of a high Reynolds number flow in a three-dimensional velocity field are typically dispersed over all possible wavelengths of the system, from the smallest scales, where viscosity dominates the advection and dissipates the energy of fluid motion, to the effective size of the system. This is not so bizarre: our everyday experience tells us it is so. On the corner of a city street, one might watch the fluttering and whirling of a discarded tram ticket as it is swept by an updraught, driven by localized thermal gradients from traffic or air-conditioning units; later, on the television news, one might see reports or predictions of storms on the city or district scale, and a weather map with isobars spanning whole continents. If you are a sailor you will know how to sail, or not, the multi-scaled surface of a turbulent ocean (Figure 1). The mechanism for this dispersal is vortex stretching and tilting: a conservative process whereby interactions between vorticity and velocity gradients create smaller and smaller eddies with amplified vorticity, until viscosity takes over (Tennekes & Lumley, 1972; Chorin, 1994).

An alternative, crude but picturesque, description of multi-scale turbulence was offered by the early 20th century meteorologist Lewis Fry Richardson (1922) in an evocative piece of doggerel: “big whirls have little whirls that feed on their velocity, and little whirls have lesser whirls and so on to viscosity.” Richardson’s

Figure 1. Turbulent action on many different scales in a high Reynolds number flow: woodcut print by Katsushika Hokusai (1760–1849).

often-quoted rhyme is apparently a parody of Irish satirist Jonathan Swift’s verse: “So, naturalists observe, a flea—Has smaller fleas that on him prey—And these have smaller still to bite”—And so proceed *ad infinitum*.”

The statistics of the velocity fluctuation distribution in turbulent flows were quantified rather more elegantly and rigorously by the mathematician Andrei N. Kolmogorov (1941b), who derived the subsequently famous “ $-5/3$ law” for the energy spectrum of the intermediate scales, or inertial scale subrange, of high Reynolds number flows which are ideally homogeneous (or statistically invariant under translation) and isotropic (or statistically invariant under rotation and reflection) in three velocity dimensions. Two thorough, but different in style and emphasis, accounts of Kolmogorov’s turbulence work are Monin & Yaglom (1971) and Frisch (1995).

Kolmogorov’s idea was that the velocity fluctuations in the inertial subrange are independent of initial and boundary conditions (i.e., they have no memory of the effects of anisotropic excitation at smaller wave numbers). The turbulent motions in this subrange, therefore, show universal statistics, and the flow is self-similar. From this premise Kolmogorov proposed the first hypothesis of similarity as: “For the locally isotropic turbulence the [velocity fluctuation] distributions F_n are uniquely determined by the quantities v_l , the kinematic viscosity, and ε , the rate of average dispersion of energy per unit mass [energy flux].” His second hypothesis of similarity is: “For pulsations [velocity fluctuations] of intermediate orders where the length scale is large compared with the scale of the finest pulsations, whose energy is directly dispersed into heat due to viscosity, the distribution laws F_n are uniquely determined by F and do not depend on v_l .”

Kolmogorov derived the form of the distribution or energy spectrum, which we denote as $\mathcal{E}(k)$, where k is the wave number given by $k^2 = k_x^2 + k_y^2 + k_z^2$, over the inertial subrange simply by dimensional analysis. By the first and second hypotheses, the spectrum must

be a function of the energy flux and wave number and independent of the viscosity or any other parameters:

$$\mathcal{E}(k) = f(\varepsilon, k).$$

By reference to the table below (after Vallis, 1999) we find

$$\begin{aligned} \mathcal{E}(k) &\sim \varepsilon^{2/3} g(k) \quad (\text{since } k \text{ is time-independent}) \\ &= C \varepsilon^{2/3} k^{-5/3}, \end{aligned} \tag{1}$$

where C is a dimensionless constant which Kolmogorov (and subsequently many others, see Sreenivasan, 1995) deduced from experimental data to be of order 1.

Quantity	Dimension
Wave number	1/length
Energy per unit mass	length ² /time ²
Energy spectrum $\mathcal{E}(k)$	length ³ /time ²
Energy flux ε	energy/time $\sim$ length ² /time ³

The physical picture associated with Equation (1) is that the kinetic energy of large-scale motions (whirls or eddies) is successively subdivided and redistributed among stepwise increasing wave number components (or smaller and smaller whirls and eddies), until the action of viscosity becomes competitive. Although this process has come to be known as the “Kolmogorov cascade,” the cascade metaphor was not used by Kolmogorov. Its first use in this context is apparently due to Onsager (1945), who also highlights another assumption underlying the $-5/3$ law: that the modulation of a given Fourier component of the velocity field is mostly due to those others that belong to wave numbers of comparable magnitude.

So Kolmogorov’s energy distribution says that ε is the only relevant parameter for turbulence in the inertial scale range. Can this really be true? Does the notorious “problem of turbulence” really boil down to such a simple relation for intermediate wavenumbers? (The fabled Problem of Turbulence was well summed up by Horace Lamb in 1932: “When I die and go to Heaven there are two matters on which I hope enlightenment. One is quantum electro-dynamics and the other is turbulence of fluids. About the former, I am really rather optimistic.”) Understandably, for a turbulence result that seems so simple and universal, so flimsily derived yet so powerful, much effort has gone into verifying the wave number spectrum, Equation (1). It is difficult to create extremely high Reynolds number flows in the laboratory, but they exist naturally in the ocean. The first and still the most exciting verification of Equation (1) was carried out by Grant et al. (1962), who made a remarkable series of measurements of turbulent velocities from a ship in the Seymour Narrows, part of the Discovery Passage on the west coast of Canada, where the Reynolds number is $\sim 10^8$ (see Figure 2). A spectral exponent close to $-5/3$ has since been measured many

Figure 2. Data re-plotted from Grant et al. (1962), showing a Kolmogorov cascade over nearly three decades. $\phi(k)$ is the measured one-dimensional spectrum function, related to the three-dimensional spectrum function as $\mathcal{E}(k) = k^2 \partial^2 \phi(k) / \partial k^2 - k \partial \phi(k) / \partial k$.

times in materially different flows with high Reynolds number (e.g., Zocchi et al. (1994) in helium).

All this would seem to wrap up the problem of turbulence in the inertial scale range. Or does it? There must surely be a catch somewhere! As usual, the devil is in the details. Kolmogorov himself made a “refinement,” as he delicately put it, of his hypotheses (Kolmogorov, 1962). It relates to the problem of small-scale intermittency, or the uneven distribution in space of the small scales. Clearly, intermittency is inherited from initial and boundary conditions, and the side-effects on ε , the assumed-constant rate of energy transfer, are not insignificant.

In fact, there is now quite a log of complaints about the $-5/3$ law, despite its all-pervasive influence on turbulence theoretical and experimental research:

- The hypothesis of local isotropy refers to infinite Reynolds number so is not applicable to a real fluid.
- No-one has ever extracted the $-5/3$ law from the Navier–Stokes equation or vice versa.
- Is it not a circular argument that to define an inertial subrange one has to assume a cascade process, and to postulate a cascade one has to assume that an inertial subrange exists?
- What about stochastic backscatter?
- Direct interaction between large and small scales can short-circuit the cascade.
- Katul et al. (2003) found that the effects of boundary conditions were evident in the inertial subrange of an atmospheric surface layer.
- The $-5/3$ law is demonstrably invalid in two dimensions. And so on.

What is the verdict on the Kolmogorov cascade? Chorin (1994, pp. 55–57) has a bet each way; in the light of experimental verifications of the $-5/3$ law, he considers that it may be correct *despite* flaws in the arguments supporting it. The scenario proposed as being entirely consistent with Kolmogorov’s theory is

that energy can and does slosh back and forth across the spectrum, once the inertial range has been set up, with the energy dissipation ε being the (presumably average) difference between energy flows in both wave number directions.

The Kolmogorov cascade is starting to sound less and less like a waterfall, which is one-way, and more and more like an energy exchange network.

KOLMOGOROV-ARNOL'D-MOSER THEOREM

In 1954, the Russian mathematician Andrei N. Kolmogorov, already famous for his contribution to measure theory and probability theory, delivered to the International Conference of Mathematics in Amsterdam, a lecture based on a paper entitled “On the General Theory of Dynamical Systems and Classical Mechanics.” In this lecture he addressed the question of how much structure remains when a “regular” (or integrable) Hamiltonian system is replaced by one that differs from the original by only a small perturbation. Kolmogorov’s original paper was not completely detailed, and clarifying work was done independently in the early 1960s by Jürgen Moser and Vladimir Arnol’d (the latter had been a student of Kolmogorov). Since then, a large body of work on this subject within the mathematical theory of Hamiltonian dynamics has been assembled.

Thus, the so-called Kolmogorov–Arnol’d–Moser (KAM) theorem is not a single theorem but rather a body of work with a common theme, which can be roughly described as the persistence of quasi-periodic motions in perturbed systems. These results were a breakthrough in the understanding of the ergodic properties of dynamical systems. The original theorems dealt with Hamiltonian systems and their discrete analogues, while more recent results have been extended to volume-preserving systems, reversible systems, and dissipative systems.

The central ideas in Kolmogorov’s original paper can be formulated as follows. Under some general assumptions, the phase space M^{2n} of an integrable Hamiltonian system is foliated by invariant tori: T^n . This system will be referred to as the unperturbed system. In the neighborhood of each torus are defined action-angle variables $(I, \phi \pmod{2\pi})$, such that the Hamiltonian H_0 is the function of only action variables I .

The motion on each torus is conditionally periodic with frequency vector $\omega(I) = \partial H_0 / \partial I$. A torus is said to be nonresonant if all the n frequencies are rationally independent (incommensurable). The unperturbed system is called nonresonant if the frequencies are functionally independent:

$$\det \left(\frac{\partial \omega}{\partial I} \right) = \det \left(\frac{\partial^2 H_0}{\partial I^2} \right) \neq 0.$$

In a nondegenerate system, the nonresonant tori form a dense set of full measure. The resonant tori form a set of measure zero, which, however, is also dense.

The system with the Hamiltonian

$$H(I, \phi, \varepsilon) = H_0(I) + \varepsilon H_1(I, \phi, \varepsilon)$$

is called the perturbed system, where the function εH_1 is the perturbation. Note that usually the perturbed system is no longer integrable. Kolmogorov’s theorem

describes the fate of the nonresonant tori under perturbation.

Theorem (A.N. Kolmogorov). *If the unperturbed system is nondegenerate, then for a sufficiently small ε most nonresonant invariant tori do not vanish but are only slightly deformed, so that in the phase space of the perturbed system there are invariant tori densely filled with conditionally periodic phase curves winding around them, with the number of independent frequencies equal to the number of degrees of freedom. These invariant tori form a majority in the sense that the measure of the complement to their union is small when the perturbation is small.*

The persistence of quasi-periodic motion is consistent with numerical experiments, well-known examples being the standard map (also called the Chirikov map) and the Hénon–Heiles system.

Discussion

KAM theory has several important implications, in particular for the stability theory. Suppose that phase space is four-dimensional. A perturbed system always has one first integral, the Hamiltonian function $H(I, \phi, \varepsilon)$ itself. The energy levels $H = h$ are three-dimensional, while the invariant tori are two-dimensional. Thus, a trajectory that starts in a region between two invariant tori of the perturbed system is forever trapped in the region between the tori. This means that the values of the action variables remain forever near their initial values, which in turn implies stability.

If, however, the number n of degrees of freedom is greater than two, the n -dimensional tori do not separate the $(2n-1)$ -dimensional energy level manifold into disjoint regions, and the invariant tori do not prevent a phase curve from wandering far away. There are examples of such drift, when the action variables change from their original value by a quantity of order 1, an effect known as “Arnol’d diffusion” (See **Arnol’d diffusion**). Although in the latter case the system is unstable, KAM theory does guarantee “metric stability,” that is, stability for most initial conditions.

Examples

1. Assume the masses of the planets are sufficiently small compared with the mass of the Sun in the gravitational n -body problem. Then a large portion of the region of phase space corresponding to unperturbed motion of all planets (on identically oriented Keplerian ellipses having small eccentricities and inclinations) is filled up by conditionally periodic motions. KAM theory provides important estimates for the long-time evolution of such a system. Note that Henri Poincaré’s groundbreaking work *Les méthodes nouvelles de la mécanique céleste* (1892) was

motivated by questions of the stability of the solar system.

2. Consider the motion of a heavy rigid body fixed at a point. If the kinetic energy of the body is sufficiently large in comparison with its potential energy at the initial moment of time, then the length of the angular momentum vector and its inclination to the horizon remain forever near their initial values, provided that the initial values of the energy and the angular momentum differ sufficiently from values for which the body can rotate around its medium principal axis.
3. For plasma confinement in toroidal chambers, the plasma particles tend to follow magnetic field lines. The equations for these magnetic field lines can be put into Hamiltonian form. When the system is azimuthally symmetric, the Hamiltonian is integrable, deviation from azimuthal symmetry creates a perturbation, and KAM theory is applicable.

KORTEWEG-DE VRIES EQUATION

Historical Introduction

The Korteweg–de Vries (KdV) equation, given here in canonical form,

$$u_t + 6uu_x + u_{xxx} = 0, \quad (1)$$

is widely recognized as a paradigm for the description of weakly nonlinear long waves in many branches of physics and engineering. Here, $u(x, t)$ is an appropriate field variable, t is the time, and x is the space coordinate in the relevant direction. It describes how waves evolve under the competing but comparable effects of weak nonlinearity and weak dispersion. Indeed, if it is supposed that x -derivatives scale as ε where ε is the small parameter characterizing long waves (i.e., typically the ratio of a relevant background length scale to a wavelength scale), then the amplitude scales as ε^2

and the time evolution takes place on a scale of ε^{-3} . The KdV equation is characterized by its family of solitary wave solutions,

$$u = a \operatorname{sech}^2(\gamma(x - Vt)), \quad \text{where } V = 2a = 4\gamma^2. \quad (2)$$

This solution describes a family of steady isolated wave pulses of positive polarity, characterized by the wave number γ ; note that the speed V is proportional to the wave amplitude a and also to the square of the wave number γ^2 .

The KdV equation (1) owes its name to the famous paper of Diederik Korteweg and Hendrik de Vries, published in 1895, in which they showed that small-amplitude long waves on the free surface of water could be described by the equation

$$\zeta_t + c\zeta_x + \frac{3c}{2h}\zeta\zeta_x + \frac{ch^2}{6}\delta\zeta_{xxx} = 0. \quad (3)$$

Here, $\zeta(x, t)$ is the elevation of the free surface relative to the undisturbed depth h , $c = (gh)^{1/2}$ is the linear long wave phase speed, and $\delta = 1 - 3B$, where $B = \sigma/gh^2$ is the Bond number measuring the effects of surface tension ($\rho\sigma$ is the coefficient of surface tension and ρ is the water density). Transformation to a reference frame moving with the speed c (i.e., (x, t) is replaced by $(x - ct, t)$, and subsequent rescaling readily establishes the equivalence of (1) and (3). Although Equation (1) now bears the name KdV, it was apparently first obtained by Joseph Boussinesq (1877) (see Miles (1980) and Pego and Weinstein (1997) for historical discussions on the KdV equation). Korteweg and de Vries found the solitary wave solutions (2), and importantly, they showed that they are the limiting members of a two-parameter family of periodic traveling-wave solutions, described by elliptic functions and commonly called cnoidal waves,

$$u = b + a \operatorname{cn}^2(\gamma(x - Vt)|m), \quad \text{where } V = 6b + 4(2m - 1)\gamma^2, \quad a = 2m\gamma^2. \quad (4)$$

Here, $\operatorname{cn}(x|m)$ is the Jacobi elliptic function of modulus m ($0 < m < 1$). As $m \rightarrow 1$, $\operatorname{cn}(x|m) \rightarrow \operatorname{sech}(x)$, and then the cnoidal wave (4) becomes the solitary wave (2), now riding on a background level b . On the other hand, as $m \rightarrow 0$, $\operatorname{cn}(x|m) \rightarrow \cos 2x$, and so the cnoidal wave (4) collapses to a linear sinusoidal wave (note that in this limit, $a \rightarrow 0$).

This solitary wave solution found by Korteweg and de Vries had earlier been obtained directly from the governing equations (in the absence of surface tension) independently by Boussinesq (1871, 1877) and Lord Rayleigh (1876), who were motivated to explain the now very well-known observations and experiments of John Scott Russell (1844). Curiously, it was not until quite recently that it was recognized that the KdV equation is not strictly valid if surface tension is taken

into account and $0 < B < \frac{1}{3}$, as then there is a resonance between the solitary wave and very short capillary waves.

After the ground-breaking work of Korteweg and de Vries, interest in solitary water waves and the KdV equation declined until the dramatic discovery of the soliton by Zabusky and Kruskal in 1965. Through numerical integrations of the KdV equation, they demonstrated that the solitary wave (2) could be generated from quite general initial conditions, and could survive intact collisions with other solitary waves, leading them to coin the term *soliton*. Their remarkable discovery, followed almost immediately by the theoretical work of Gardner et al. (1967) showing that the KdV equation was *integrable* through an inverse scattering transform, led to many other startling discoveries and marked the birth of soliton theory as we know it today (See **Solitons, a brief history**). The implication is that the solitary wave is the key component needed to describe the behavior of long, weakly nonlinear waves.

An alternative to the KdV equation is the Benjamin-Bona-Mahony (BBM) equation in which the linear dispersive term $c\zeta_{xxx}$ in (3) is replaced by $-\zeta\zeta_{xx}$. It has the same asymptotic validity as the KdV equation, and since it has rather better high wave number properties, it is somewhat easier to solve numerically. However, it is not integrable and, consequently, has not attracted the same interest as the KdV equation.

Both the KdV and BBM equations are uni-directional. A two-dimensional version of the KdV equation is the KP equation (Kadomtsev & Petviashvili, 1970),

$$(u_t + 6uu_x + u_{xxx})_x \pm u_{yy} = 0. \quad (5)$$

This equation includes the effects of weak diffraction in the y -direction, in that y -derivatives scale as ε^2 whereas x -derivatives scale as ε . Like the KdV equation it is an integrable equation. When the “+”-sign holds in (5), this is the KP2 equation, and it can be shown that then the solitary wave (2) is stable to transverse disturbances. On the other hand, if the “-”-sign holds, this is the KP1 equation for which the solitary wave is unstable; instead this equation supports “lump” solitons. Both KP1 and KP2 are integrable equations. To take account of stronger transverse effects and/or to allow for bi-directional propagation in the x -direction, it is customary to replace the KdV equation with a Boussinesq system of equations; these combine the long wave approximation to the dispersion relation with the leading-order nonlinear terms and occur in several asymptotically equivalent forms.

Although the KdV equation (1) is historically associated with water waves, it in fact occurs in many other physical contexts, where it arises as an asymptotic multiscale reduction from the relevant

governing equations. Typically, the outcome is

$$A_t + cA_x + \mu AA_x + \lambda A_{xxx} = 0. \quad (6)$$

Here, c is the relevant linear long wave speed for the mode whose amplitude is $A(x, t)$, while μ and λ , the coefficients of the quadratic nonlinear and linear dispersive terms, respectively, are determined from the properties of this same linear long wave mode and, like c , depend on the particular physical system being considered. Note that the linearization of (6) has the linear dispersion relation $\omega = ck - \lambda k^3$ for linear sinusoidal waves of frequency ω and wave number k ; this expression is just the truncation of the full dispersion relation for the wave mode being considered, and immediately identifies the origin of the coefficient λ . Similarly, the coefficient μ can be identified with the an amplitude-dependent correction to the linear wave speed. Transformation to a reference frame moving with a speed c and subsequent rescaling shows that (6) can be transformed to the canonical form (1). Equations of the form (6) arise in the study of internal solitary waves in the atmosphere and ocean, mid-latitude and equatorial planetary waves, plasma waves, ion-acoustic waves, lattice waves, waves in elastic rods, and in many other physical contexts (see, for instance, Ablowitz & Segur, 1981; Dodd et al., 1982; Drazin & Johnson, 1989; Grimshaw, 2001).

In some physical situations, it is necessary to complement the KdV equation (6) with a higher-order cubic nonlinear term of the form $\nu A^2 A_x$. After transformation and rescaling, the amended equation (6) can be transformed to the so-called Gardner equation

$$u_t + 6uu_x + 6\delta u^2 u_x + u_{xxx} = 0. \quad (7)$$

Like the KdV equation, the Gardner equation is integrable by the inverse scattering transform. Here the coefficient δ can be either positive or negative, and the structure of the solutions depends crucially on which sign is appropriate. Again, in some physical situations, solitary waves propagate through a variable environment which means that the coefficients c , μ , and λ in (6) are functions of x , while an additional term $c(\sigma_x/2\sigma)A$ needs to be included, where $\sigma(x)$ is a magnification factor. After transforming to new variables, $\theta = (\int^x dx/c) - t$, x with $U = \sigma^{1/2}u$, the variable-coefficient KdV equation is obtained,

$$U_x + \alpha(x)U\theta_\theta + \beta(x)U_{\theta\theta\theta} = 0. \quad (8)$$

Here, $\alpha = \mu/c\sigma^{1/2}$, $\beta = \lambda/c^3$. In general, this is not an integrable equation and must be solved numerically, although we shall exhibit some asymptotic solutions below. Another modification of the KdV equation occurs when it is necessary to take account of background rotation, leading to the rotation-modified KP equation (see, for instance, Grimshaw, 2001), in which a term $-f^2u$ is added to the left-hand side of Equation (5), where f is a measure of the background rotation.

Solitons

The remarkable discovery of Gardner et al. (1967) that the KdV equation was integrable through an inverse scattering transform marked the beginning of soliton theory. Their pioneering work was followed by the work of Zakharov and Shabat (1972) which showed that another well-known nonlinear wave equation, the nonlinear Schrödinger equation, was also integrable by an inverse scattering transform. Their demonstration that the integrability of the KdV equation was not an isolated result, was followed closely by analogous results for the modified KdV equation (Wadati, 1972) and the sine-Gordon equation (Ablowitz et al., 1973). In 1974, Ablowitz, Kaup, Newell, and Segur provided a generalization and unification of these results in the AKNS scheme. From this point there has been an explosive and rapid development of soliton theory in many directions (see, for instance, Ablowitz & Segur, 1981; Dodd et al., 1982; Newell, 1985; Drazin & Johnson, 1989).

For the KdV equation (1) the starting point is the Lax pair (Lax, 1968) for an auxiliary function $\phi(x, t)$,

$$L\phi \equiv -\phi_{xx} - u\phi = \lambda\phi, \quad (9)$$

$$\phi_t = B\phi \equiv (u_x + C)\phi + (4\lambda - 2u)\phi_x. \quad (10)$$

Here, $C(t)$ depends on the normalization of ϕ . The first of these equations (9), with suitable boundary conditions at infinity (see below) defines a spectral problem for ϕ in the spatial variable x with a spectral parameter λ , and with the time variable t as a parameter. The second equation (10) then describes how the spectral function ϕ evolves in time. If it is now assumed that λ is independent of time (i.e., $\lambda_t = 0$) then the KdV equation (1) is just the compatibility condition for these two equations (9, 10); that is, it emerges as a result of the condition that $(\phi_{tx})_t = (\phi_t)_{xx}$. In terms of the operators L , B defined in the Lax pair (9, 10), the KdV equation can be written in the symbolic form $L_t = BL - LB$ (Lax, 1968). This form indicates the path to further generalizations, in that other nonlinear wave equations can be obtained by choosing different operators L , B . The general strategy for integration of the KdV equation now consists of three steps. Here, we will describe the process under the hypothesis that we seek solutions $u(x, t)$ of the KdV equation (1), which decay to zero sufficiently fast as $x \rightarrow \pm\infty$ and have the initial condition $u(x, 0) = u_0(x)$. First, we insert the initial condition into the spectral problem (9) to obtain the scattering data (these will be defined precisely below). Then (10) is used to move the scattering data forward in time; it transpires that is a very simple process, and note in particular that the spectral parameter λ is independent of t and hence is determined by the initial condition. The third step is to invert the scattering data at time $t > 0$ and so recover $u(x, t)$; this is the most difficult step, but for the KdV equation can be reduced

to solution of a linear integral equation. Thus, the three steps constitute a linear algorithm for the solution of the KdV equation, and it is in this sense that it is said that the Lax pair (9,10) constitutes integrability of the KdV equation.

The spectral problem (9) for the KdV equation consists of two parts. The *discrete* spectrum is found by seeking solutions such that $\phi \rightarrow 0$ as $x \rightarrow \pm\infty$, which requires that $\lambda < 0$. It can be shown that there then exists a *finite* set of discrete eigenvalues $\lambda = -\kappa_n^2$, $n = 1, 2, \dots, N$, and corresponding real eigenfunctions ϕ_n such that

$$\phi_n \sim c_n \exp(-\kappa_n x) \quad \text{as } x \rightarrow \infty. \quad (11)$$

There is a similar condition as $x \rightarrow -\infty$, namely, that $\phi_n \sim d_n \exp(\kappa_n x)$. The real constants c_n, d_n are determined once the normalization condition is satisfied, that is,

$$\int_{-\infty}^{\infty} \phi_n^2 dx = 1. \quad (12)$$

The continuous spectrum consists of all $\lambda > 0$, and so we set $\lambda = k^2$ where k is real. Then we define the scattering problem for solutions $\phi(x; k)$ of (9) by the boundary conditions,

$$\phi \sim \exp(-ikx) + R(k) \exp(ikx) \quad \text{as } x \rightarrow \infty, \quad (13)$$

$$\phi \sim T(k) \exp(-ikx) \quad \text{as } x \rightarrow -\infty. \quad (14)$$

The scattering data then consists of the set $(\kappa_n, c_n, n = 1, 2, \dots, N)$ together with the reflection coefficient $R(k)$. It is useful to note that $R(k)$ may be continued into the upper half of the complex k -plane, has there a set of simple poles at $k = i\kappa_n$, and $R \rightarrow 1$ as $|k| \rightarrow \infty$.

The next step is to determine from (10) how the scattering data evolves in time (note that the dependence on time t has been suppressed in the preceding paragraph). First, we recall that the discrete eigenvalues κ_n are independent of t . Next, we multiply (10) by ϕ_n and integrate the result over all x ; also, on using (9), it is readily found that

$$\frac{d}{dt} \int_{-\infty}^{\infty} \phi_n^2 dx = C_n \int_{-\infty}^{\infty} \phi_n^2 dx,$$

where the constant C in (10) here must be indexed with n to become C_n . But then the normalization condition (12) implies that $C_n = 0$. Now substitute (11) into (10) to show that

$$\begin{aligned} \frac{dc_n}{dt} &= 4\kappa_n^3 c_n \\ \text{so that } c_n(t) &= c_n(0) \exp(\kappa_n^3 t). \end{aligned} \quad (15)$$

For the continuous spectrum, the asymptotic expressions (13), (14) are substituted into (10). Now it is found

that the constant $C(k) = 4ik^3$, and that

$$\frac{dR}{dt} = 8ik^3 R$$

$$\text{so that } R(k; t) = R(0; k) \exp(8ik^3 t). \quad (16)$$

Similarly, it can be shown that $T(k; t) = T(k; 0)$.

The final step is the inversion of the scattering data at time t to recover the potential $u(x, t)$ in 9). This is accomplished through the Marchenko integral equation for the function $K(x, y)$

$$\begin{aligned} K(x, y) + F(x + y) + \int_x^\infty K(x, z) F(y + z) dz \\ = 0. \end{aligned} \quad (17)$$

Here the function $F(x)$ is known in terms of the scattering data at time t ,

$$\begin{aligned} F(x) = \sum_{n=1}^N c_n^2(t) \exp(-\kappa_n x) \\ + \frac{1}{2\pi} \int_{-\infty}^{\infty} R(k; t) \exp(ikx) dk. \end{aligned} \quad (18)$$

Here the t -dependence of K, F has been suppressed as the linear integral equation (17) is solved with t fixed. Then

$$u(x, t) = 2 \frac{\partial}{\partial x} \{K(x, x; t)\}, \quad (19)$$

where the t -dependence in K has been restored.

The inverse scattering transform described by (17), (18) enables one to find the solution of the KdV equation (1) for an arbitrary localized initial condition. The most important outcome is that as $t \rightarrow \infty$, the solution evolves into N rank-ordered solitons propagating to the right ($x > 0$), and some decaying radiation propagating to the left ($x < 0$),

$$\begin{aligned} u \sim \sum_{n=1}^N 2\kappa_n^2 \operatorname{sech}^2(\kappa_n(x - 4\kappa_n^2 t - x_n)) \\ + \text{radiation}. \end{aligned} \quad (20)$$

Here the N solitons are derived directly from the discrete spectrum, where each eigenvalue $-\kappa_n$ generates a soliton of amplitude $2\kappa_n^2$, while the phase shifts x_n are determined from the constants $c_n(0)$. The continuous spectrum is responsible for the decaying radiation, which decays at each fixed $x < 0$ as $t^{-1/3}$.

The important special case when the reflection coefficient $R(k) \equiv 0$ leads to the N -soliton solution, for which there is no radiation. Indeed, the N -soliton solution can be obtained as an explicit solution of the Marchenko equation (17). We illustrate the procedure for $N = 1, 2$. First, for $N = 1$, $F(x) = c^2 \exp \kappa(x - 4\kappa^2 t)$, where we have omitted the subscript $n = 1$ for simplicity. Then seek a solution of

(17) in the form $K(x, y, t) = L(x, t) \exp(-\kappa y)$, where L can be found by simple algebra. The outcome is that

$$L(x, t) = \frac{-2\kappa c(0)^2 \exp(-\kappa x + 8\kappa^2 t)}{2\kappa + c(0)^2 \exp(-2\kappa x + 8\kappa^2 t)}.$$

Finally u is found from (19),

$$u = 2\kappa^2 \operatorname{sech}^2(\kappa(x - 4\kappa^2 t) - x_1).$$

This is just the solitary wave (2) of amplitude $2\kappa^2$; the phase shift x_1 is such that $c(0)^2 = 2\kappa \exp(2\kappa x_1)$. The procedure for $N=2$ follows a similar course. Thus, with $R \equiv 0$, $N=2$ in F (18), seek a solution of the Marchenko equation (17) in the form $K(x, y, t) = L_1(x, t) \exp(-\kappa_1 y) + L_2(x, t) \exp(-\kappa_2 y)$, and again $L_{1,2}$ can be found by simple algebra. The outcome is the two-soliton solution. For instance, with $\kappa_1 = 1$, $\kappa_2 = 2$, this is

$$u = 12 \frac{3 + 4\cosh(2x - 8t) + \cosh(4x - 64t)}{[3\cosh(x - 28t) + \cosh(3x - 36t)]^2}. \quad (21)$$

It can be readily shown that

$$u \sim 8\operatorname{sech}^2(2(x - 16t \mp x_2) + 2\operatorname{sech}^2(x - 4t \mp x_1) \quad \text{as } t \rightarrow \pm\infty, \quad (22)$$

where the phase shifts $x_{1,2} = (-\frac{1}{2}, \frac{1}{4}) \ln 3$. Thus, the two-soliton solution describes the elastic collision of two solitons, in which each survives the interaction intact, and the only memory of the collision is the phase shifts; note that $x_1 < 0$, $x_2 > 0$, so that the larger soliton is displaced forward and the smaller soliton is displaced backward. The general case of an N -soliton is analogous and is essentially a sequence of pair-wise two-soliton interactions.

The integrability of the KdV equation (1) is also characterized by the existence of an infinite set of independent conservation laws. The most transparent conservation laws are

$$\int_{-\infty}^{\infty} u \, dx = \text{constant}, \quad (23)$$

$$\int_{-\infty}^{\infty} u^2 \, dx = \text{constant}, \quad (24)$$

$$\int_{-\infty}^{\infty} \left(u^3 - \frac{1}{2} u_x^2 \right) dx = \text{constant}, \quad (25)$$

which may be associated with the conservation of mass, momentum, and energy, respectively. Indeed (23) is obtained from the KdV equation (1) by integrating over x , while (24), (25) are obtained in an analogous manner after first multiplying (1) by u , u^2 , respectively. However, it transpires that these are just the first three conservation laws in an infinite set, where each successive conservation law contains a higher power of u than the preceding one. This may be demonstrated

using the inverse scattering transform (see Ablowitz & Segur, 1981; Dodd et al., 1982; Newell, 1985). However, here we use the original method based on the Miura transformation as adapted by Gardner. The Miura transformation is

$$u = -v_x - v^2, \quad (26)$$

$$v_t - 6v^2 v_x + v_{xxx} = 0. \quad (27)$$

Here (27) is the modified KdV equation. Direct substitution of (26) into the KdV equation shows that if v solves the modified KdV equation (27), then u solves the KdV equation (1). This discovery was the starting point for the discovery of the inverse scattering transform, since if one considers (26) as an equation for v and writes $v = \phi_x / \phi$, followed by a Galilean transformation for u (i.e., $u \rightarrow u - \lambda$, $x \rightarrow x - 6\lambda t$), one obtains the spectral problem (9). Here we follow a different route and write

$$v = \frac{1}{2\varepsilon} - \varepsilon w,$$

which (after a shift $x \rightarrow x + 3t/2\varepsilon^2$) converts the mKdV equation (27) into the Gardner equation (7) with $\delta = -\varepsilon^2$. Apart from a constant, which may be removed by a Galilean transformation, the corresponding expression for u is the Gardner equation,

$$u = w + \varepsilon w_x - \varepsilon^2 w^2. \quad (28)$$

Thus, if w solves the Gardner equation

$$w_t + 6w w_x - 6\varepsilon^2 w^2 w_x + w_{xxx} = 0, \quad (29)$$

then u solves the KdV equation (1).

Next, we observe that the Gardner equation (29) has the conservation law

$$\int_{-\infty}^{\infty} w \, dx = \text{constant}. \quad (30)$$

Since $w \rightarrow u$ as $\varepsilon \rightarrow 0$, we write the formal asymptotic expansion

$$w \sim \sum_{n=0}^{\infty} \varepsilon^n w_n.$$

It follows from (30) that then

$$\int_{-\infty}^{\infty} w_n \, dx = \text{constant},$$

for each $n = 0, 1, 2, \dots$. But substitution of this same asymptotic expansion for w into (28) generates a sequence of expressions for w_n in terms of u , of which the first few are

$$w_0 = u, \quad w_1 = -u_x, \quad w_2 = -u^2 + u_{xx}.$$

Thus, we see that $n=0, 2$ give the conservation laws (23), (24), respectively, while $n=1$ is an exact differential. It may now be shown that all even values of

n yield nontrivial and independent conservation laws, while all odd values of n are exact differentials.

The KdV equation belongs to a class of nonlinear wave equations, which have Lax pairs and are integrable through an inverse scattering transform. It shares with these equations several other remarkable features, such as the Hirota bilinear form, Bäcklund transformations, and the Painlevé property. Detailed descriptions of these and other properties of the KdV equation can be found in the other entries and referenced texts.

Solitary Waves in a Variable Environment

In a variable environment, the governing equation which replaces (1) is the variable-coefficient KdV equation (8). In general, this is not an integrable equation and is usually solved numerically. However, there are two distinct limiting situations in which some analytical progress can be made. First, let it be supposed that the coefficients $\alpha(x), \beta(x)$ in (8) vary rapidly with respect to the wavelength of a solitary wave, and then consider the case when these coefficients make a rapid transition from the values α_-, β_- in $x < 0$ to the values α_+, β_+ in $x > 0$. Then a steady solitary wave can propagate in the region $x < 0$, given by

$$U = a \operatorname{sech}^2(\gamma(\theta - Wx)),$$

$$\text{where } W = \frac{\alpha_- a}{3} = 4\beta_- \gamma^2. \quad (31)$$

It will pass through the transition zone $x \approx 0$ essentially without change. However, on arrival into the region $x > 0$, it is no longer a permissible solution of (8), which now has constant coefficients α_+, β_+ . Instead, with $x=0$, expression (31) now forms an effective initial condition for the new constant-coefficient KdV equation. Using the spectral problem (9) and the inverse scattering transform, the solution in $x > 0$ can now be constructed; indeed, in this case, the spectral problem (9) has an explicit solution (e.g., Drazin & Johnson, 1989). The outcome is that the initial solitary wave *fissions* into N solitons and some radiation. The number N of solitons produced is determined by the ratio of coefficients $R = \alpha_+ \beta_- / \alpha_- \beta_+$. If $R > 0$ (i.e., there is no change in polarity for solitary waves), then $N = 1 + [(8R + 1)^{1/2} - 1]/2$ ($[\dots]$ denotes the integral part); as R increases from 0, a new soliton (initially of zero amplitude) is produced as R successively passes through the values $m(m+1)/2$ for $m = 1, 2, \dots$. But if $R < 0$ (i.e., there is a change in polarity), no solitons are produced and the solitary wave decays into radiation. For instance, for water waves, $c = (gh)^{1/2}$, $\mu = 3c/2h$, $\lambda = ch^2/6$, $\sigma = c$, and so $\alpha = 3/(2hc^{1/2})$, $\beta = h^2/(6c^2)$, where h is the water depth. It can then be shown that a solitary water wave propagating from a depth h_- to a depth h_+ will fission into N solitons where N is given as above with $R = (h_-/h_+)^{9/4}$; if $h_- > h_+$, $N \geq 2$, but

if $h_- < h_+$ then $N = 1$ and no further solitons are produced (Johnson, 1973).

Next, consider the opposite situation when the coefficients $\alpha(x), \beta(x)$ in (8) vary slowly with respect to the wavelength of a solitary wave. In this case a multi-scale perturbation technique (see Grimshaw, 1979, or Grimshaw & Mitsudera, 1993) can be used in which the leading term is

$$U \sim A \operatorname{sech}^2 \gamma \left(\theta - \int_{x_0}^x W dx \right), \quad (32)$$

where

$$W = \frac{\alpha A}{3} = 4\beta \gamma^2. \quad (33)$$

Here the wave amplitude $a(x)$ and, hence, also $W(x), \gamma(x)$ are slowly varying functions of x . Their variation is most readily determined by noting that the variable-coefficient KdV equation (8) possesses a conservation law,

$$\int_{-\infty}^{\infty} U^2 d\theta = \text{constant}, \quad (34)$$

which expresses conservation of wave-action flux. Substitution of (32) into (34) gives

$$\frac{2A^2}{3\gamma} = \text{constant},$$

$$\text{so that } A = \text{constant} \left(\frac{\beta}{\alpha} \right)^{1/3}. \quad (35)$$

This is an explicit equation for the variation of the amplitude $A(x)$ in terms of $\alpha(x), \beta(x)$. However, the variable-coefficient KdV equation (8) also has a conservation law for mass,

$$\int_{-\infty}^{\infty} U d\theta = \text{constant}. \quad (36)$$

Thus, although the slowly varying solitary wave conserves wave-action flux, it cannot simultaneously conserve mass. Instead, it is accompanied by a trailing shelf of small amplitude but long length scale given by U_s , so that the conservation of mass gives

$$\int_{-\infty}^{\phi} U_s d\theta + \frac{2A}{\gamma} = \text{constant},$$

where $\phi = \int_{x_0}^x W dx$ ($\theta = \phi$ gives the location of the solitary wave) and the second term is the mass of the solitary wave (32). Differentiation then yields the amplitude $U_- = U_s(\theta = \phi)$ of the shelf at the rear of the solitary wave,

$$U_- = \frac{3\gamma_x}{\alpha\gamma^2}. \quad (37)$$

This shows that if the wavelength γ^{-1} increases (decreases) as the solitary wave deforms, then the trailing shelf amplitude U_- has the opposite (same)

polarity as the solitary wave. Once U_- is known, the full shelf $U_s(\theta, x)$ is found by solving (8) with the boundary condition that $U_s(\theta = \phi) = U_-$ (see El & Grimshaw, 2002, where it is shown that the trailing shelf may eventually generate secondary solitary waves).

For a solitary water wave propagating over a variable depth $h(x)$, these results show that the amplitude varies as h^{-1} , while the trailing shelf has positive (negative) polarity relative to the wave itself accordingly as $h_x < (>) 0$. A situation of particular interest occurs if the coefficient $\alpha(x)$ changes sign at some particular location (note that in most physical systems the coefficient β of the linear dispersive term in (8) does not vanish for any x). This commonly arises for internal solitary waves in the coastal ocean, where typically in the deeper water, $\alpha < 0$, $\beta > 0$ so that internal solitary waves propagating shorewards are waves of depression. But in shallower water, $\alpha > 0$ and so only internal solitary waves of elevation can be supported. The issue then arises as to whether an internal solitary wave of depression can be converted into one or more solitary waves of elevation as the critical point, where α changes sign, is traversed. This problem has been intensively studied (see, for instance, Grimshaw et al., 1998 and the references therein), and the solution depends on how rapidly the coefficient α changes sign. If α passes through zero rapidly compared with the local width of the solitary wave, then the solitary wave is destroyed and converted into a radiating wave train (see the discussion above in the first paragraph of this section). On the other hand, if α changes sufficiently slowly for the present theory to hold (i.e., (35) applies), we find that as $\alpha \rightarrow 0$, then $A \rightarrow 0$ in proportion to $|\alpha|^{1/3}$, while $U_- \rightarrow \infty$ as $|\alpha|^{-8/3}$. Thus, as the solitary wave amplitude decreases, the amplitude of the trailing shelf, which has the opposite polarity, grows indefinitely until a point is reached just prior to the critical point where the slowly varying solitary wave asymptotic theory fails. A combination of this trailing shelf and the distortion of the solitary wave itself then provide the appropriate "initial" condition for one or more solitary waves of the opposite polarity to emerge as the critical point is traversed. However, it is clear that in situations, as here, where $\alpha \approx 0$, it will be necessary to include a cubic nonlinear term in (8), thus converting it into a variable-coefficient Gardner equation (cf. (7)). This case has been studied by Grimshaw et al. (1999), who show that the outcome depends on the sign of the coefficient (ν) of the cubic nonlinear term at the critical point. If $\nu > 0$, so that solitary waves of either polarity can exist when $\alpha = 0$, then the solitary wave preserves its polarity (i.e., remains a wave of depression) as the critical point is traversed. On the other hand, if $\nu < 0$, so that no solitary wave can exist when $\nu = 0$, then the solitary wave of depression may be converted into one or more solitary waves of elevation.

KURAMOTO-SIVASHINSKY EQUATION

Derived by Yoshiki Kuramoto and Takeo Tsuzuki in the context of reaction-diffusion systems (Kuramoto & Tsuzuki, 1975, 1976), and by Gregory Sivashinsky in the study of flame front propagation (Sivashinsky, 1977), the Kuramoto-Sivashinsky equation (KS) is a prime example of a system that possesses a rich variety of spatial and temporal behaviors. The mathematical and statistical (thermodynamic) analyses and classification of both elementary solutions and observed complex behaviors have generated many advances in the understanding of the often complex patterns that arise in many experimental simulations.

The KS equation in one spatial dimension may be written

$$u_t + uu_x + u_{xx} + u_{xxx} = 0, \quad (1)$$

where the subscripts denote the partial derivatives w.r.t. the space variable x , and the time variable t . One important class of solutions is defined by a periodic boundary condition, say, with a $2\pi L$ -periodicity. Here we may interpret such solutions as being restricted to a cell of size $2\pi L$ and the cellular state size serving as the control (or bifurcation) parameter. For small values of $L > 0$, the solutions of (1) behave periodically; then as L is increased, the system passes through a wide variety of behavior including exhibiting spatiotemporal chaos. Via a simple rescaling, the parameter dependence can be made explicit in (1), and the solutions then satisfy $u(x, t) = u(x + 2\pi, t)$. Equation (1) possesses both translation and Galilean symmetries.

Physically, the form of Equation (1) models the small perturbations from a reference Poiseuille flow of a film layer on an inclined plane (Pumir et al., 1983). The name KS often refers in the literature to the closely related equation formed by letting $u = w_x$

in (1) and integrating. Higher-dimensional equivalents of this form are found in the independent derivations of Kuramoto and Sivashinsky. The first is in the context of angular-phase turbulence for a system of reaction-diffusion equations modeling the Belousov-Zabotinsky reaction in three spatial dimensions. Here, the solution is considered to be a small perturbation of a global periodic solution. The Sivashinsky laminar flame front derivation models small thermal diffusive instabilities, where the solution is the perturbation of an unstable planar front in the direction of propagation. Further derivations of the system can be found in the review by Nicolaenko (1986) and references therein.

The KS equation has been shown to possess an inertial manifold, that is, the infinite-dimensional solution space of the system is spanned by the solutions to a coupled system of ordinary differential equations with a low number of degrees of freedom (Foias et al., 1988). Hence, the system may be effectively studied by Fourier mode expansion, where the number of Fourier modes determining the dynamics is proportional to L .

The nontrivial behavior of the KS equation stems from the linear instability of the laminar state $u(x, t) = \text{constant}$ —the evolution of the system is governed by the quadratic nonlinear coupling term uu_x and a second-order instability term u_{xx} that is balanced by the dissipation term u_{xxx} . Long-wavelength k -numbered modes with $k < L$ are unstable. However, the linearly unstable low modes of the system are stabilized by the strong nonlinear coupling while the extremely stable high modes, with intermediate wavelengths with mode number $k \sim L$ play the important role of maintaining a “chaotic dynamical equilibrium.”

For $L \geq 1$, standing and traveling waves may coexist with solutions having complicated oscillatory behavior. For example, antisymmetrically pulsating standing waves and waves that change both form and velocity periodically with time are considered in Demekhin et al. (1991). There exist windows of the parameter L in which many of these cellular states are stable. Windows of intermittency and strange (chaotic) attractors are also observed. For L not too large, these complex motions can be reached quite suddenly after extremely long transients. Figure 1 displays typical evolution once transients have died away. The KS equation also possesses persistent homoclinic and heteroclinic saddle connections which can be effectively explained via symmetry arguments (Kevrekidis et al., 1990).

The KS equation may be damped by the addition of the term νu on the left-hand side of (1), where ν parameterizes the level of damping. For zero damping the KS equation exhibits highly chaotic motions for large L . In the transition to these weakly turbulent motions, temporal intermittency is observed. Here, chaotic motions passing close to simple and weakly unstable states will feel regularizing effects for a

Figure 1. Spatiotemporally chaotic solution $u(x, t)$, computed from a 64-d Fourier truncation at $L = 10$. Coordinate x horizontal, amplitude u vertical, with plots of different times t overlapped at t progresses.

short while, for example. However, for large L and with damping, the intermittent behavior in the transition to weak turbulence also has a spatial element (Chaté & Manneville, 1986). In this scenario, a fluctuating mixture of both regular and chaotic patches with well-defined boundaries are observed in the solution surface $u(x, t)$. Choosing the parameters so that a weakly turbulent solution can be reached by spatiotemporal intermittency, one will observe chaotic domains slowly occupying the system; setting parameter values below such a threshold one will see the domains recede.

L

LABORATORY MODELS OF NONLINEAR WAVES

In the decade following his 1834 discovery of the hydrodynamic solitary wave on Edinburgh's Union Canal, John Scott Russell constructed a water tank, allowing nonlinear wave phenomena to be studied in a laboratory environment (Russell, 1844). Among other results of these experiments, Russell observed, first, that the speed (v) of a solitary wave is related to its height (h) by the empirical relation $v = \sqrt{g(d+h)}$, where d is the resting depth of the water and g is the acceleration of gravity. Second, two solitary waves pass smoothly through each other without scattering. Third, two or more solitary waves can be generated from a sufficiently large "initial heap" of water. In the case sketched in Figure 1, for example, a volume (V) of water is released (by raising a sliding panel at the left-hand side of the tank) that is sufficiently large to generate two hydrodynamic solitons but not large enough to generate three of them. Also the soliton of larger amplitude is observed to have a higher velocity, leading to a separation between the two components that increases with time.

Since Russell's seminal work, hydrodynamic wave tanks have been widely used to investigate nonlinear wave propagation in a variety of settings, and several tanks suitable for undergraduate laboratories have been developed and described (Bettini et al., 1983; Olsen et al., 1984; Remoissenet, 1999). Tank experiments allow students to quantitatively investigate various properties of the Korteweg-de Vries (KdV) equation, which can be written in normalized form as

$$\frac{\partial u}{\partial t} + \frac{\partial u}{\partial x} + u \frac{\partial u}{\partial x} + \frac{\partial^3 u}{\partial x^3} = 0, \quad (1)$$

Figure 1. A sketch of John Scott Russell's wave tank, generating two solitons.

where $u(x, t)$ represents the vertical displacement of the wave from its resting level. Such experiments include quantitative comparisons of the number of solitons produced by an initial amount of water V as determined by eigenvalues of the corresponding time-independent linear Schrödinger equation through the inverse scattering transform method (Olsen et al., 1984). Similar tank experiments on deep water (where the depth is much larger than the lateral extent of the waves) allow quantitative studies of the nonlinear Schrödinger equation (Remoissenet, 1999).

In addition to wave tanks, mechanical wave models have been constructed for other nonlinear systems, including mechanical models of the normalized sine-Gordon (SG) equation

$$\frac{\partial^2 u}{\partial x^2} - \frac{\partial^2 u}{\partial t^2} = \sin u. \quad (2)$$

As shown in the model of Figure 2, a number of pendula (dressmaker pins) are connected to a longitudinal spring (elastic band), whereupon $u(x, t)$ is the angle of rotation of the pendulum located at position x as a function of time t . The first term in Equation (2) represents the elastic restoring torque between adjacent pendula, the second term represents their angular acceleration, and the right-hand term is the angular-dependent torque of gravity. With a bit of practice, this simple model allows one to observe and demonstrate kink propagation, kink-kink collisions, breathers, and kink-antikink annihilation (Scott, 1969, 1970). The latter, in turn, is a model for electron-positron annihilation in elementary-particle physics.

More detailed mechanical models of the SG equation have been designed and constructed, which are suitable for undergraduate laboratory experiments (Scott, 1969, 1970; Remoissenet, 1999). As is evident from Figure 3, such models allow quantitative studies of the Lorentz contraction experienced by a kink as it approaches the limiting speed (Mach 1) of the system. For research purposes, Matteo Cirillo developed a mechanical model of fluxon propagation on a long Josephson junction, including an adjustable torque on the pendula (from air jets) that models the bias current acting in a

Figure 2. A kink on a simple mechanical model of the sine-Gordon equation that can be made from dressmaker pins and an elastic band.

Figure 3. Strobe photos of an SG kink propagating on a mechanical model that was designed for student experiments (Scott, 1969). The kink is traveling to the right and slowing down due to friction. Spacing between the pendula is 1.59 cm and the time between successive images is 0.6 s.

typical experiment (Cirillo et al., 1981). Also, Michel Remoissenet and his colleagues have developed a model of the nonlinear Klein-Gordon equation with a double-well potential (the “phi-fourth model”) to study the properties of compactons and the propagation of domain walls in ferroelectric and ferromagnetic materials (Duseul, 1998).

Complementing the family of mechanical models for nonlinear wave phenomena are nonlinear electrical transmission lines (Scott, 1970; Ostrovsky et al., 1972; Lonngren, 1978; Remoissenet, 1999). In energy-conserving versions of these models, nonlinearity is usually introduced through voltage-dependent capacitors (varactor diodes), and models of the KdV equation, Boussinesq equations, and the Toda lattice are readily constructed.

Allowing energy dissipation, it has long been known that the candle (or dynamite fuse or Japanese incense) models the leading edge of a nerve impulse as described by the Zeldovich-Frank-Kamenetsky (ZF) equation

$$\frac{\partial^2 u}{\partial x^2} - \frac{\partial u}{\partial t} = u(u-a)(u-1), \quad (3)$$

where $u(x, t)$ represents temperature of a candle flame or transmembrane voltage of a nerve impulse. This equation can also be modeled by a nonlinear electrical transmission in which the transverse (shunt)

conductive element is nonlinear with a region of negative slope (negative differential conductance) as provided by an Esaki tunnel diode or by a Giaever-type superconductive diode (Scott, 1970; Remoissenet, 1999).

In the 1920s, R.S. Lilly showed that nerve impulse propagation can be modeled by a piece of iron wire immersed in a strong nitric- or sulfuric-acid solution (Lilly, 1925). At rest, the wire is stabilized (passivated) by a thin oxide layer that prevents further oxidation. If this passivated layer is disturbed by mechanical or electrical means, however, a deoxidized region propagates along the wire, followed by re-establishment of the stabilizing oxide layer. In this manner, the iron-wire model simulates the recovery property of biological nerves that is missed by Equation (3).

A more complete electrical representation of impulse conduction along a nerve fibre was developed by Jin-ichi Nagumo and his colleagues in collaboration with Richard FitzHugh (Nagumo et al., 1962). Known as the FitzHugh-Nagumo equation, this model augments the ZF equation to allow for recovery to the initial resting state. Finally, the neuristor is an electronic device that functions like a nerve fiber and can be used as the basic element in a family of computing elements.

LANDAU–LIFSHITZ EQUATION

The principal assumption of macroscopic ferromagnetism theory is that a magnetic crystal state is described unambiguously by the magnetization vector $\mathbf{M}$, so the dynamics and kinetics of a ferromagnet are determined by variations in its magnetization. The magnetization of a ferromagnet as a function of space coordinates and time $\mathbf{M}(\mathbf{x}, t)$ is a solution of the Landau–Lifshitz (LL) equation, which was first used by Soviet scientists Lev Landau and Evgeni Lifshitz for describing the dynamics of a small velocity domain wall, the magnetic susceptibility of ferromagnets with a domain structure, and ferromagnetic resonance (Landau & Lifshitz, 1935). Later, the macroscopic theory of spin waves as small vibrations of the magnetization vector was developed on the basis of the linearized LL equation (Akhieser et al., 1968). At present, the LL equation is the theoretical foundation of phenomenological magnetization dynamics in magnetically ordered solids, including ferromagnets, antiferromagnets, and ferrites.

The LL equation in a ferromagnet has the following form:

$$\frac{\partial \mathbf{M}}{\partial t} = -\frac{2\mu_0}{\hbar} [\mathbf{M} \times \mathbf{H}_{\text{eff}}] - \gamma [\mathbf{M} \times [\mathbf{M} \times \mathbf{H}_{\text{eff}}]], \quad (1)$$

where μ_0 is the Bohr magneton and γ is the relaxation constant determining the damping motion of the vector $\mathbf{M}$. The effective magnetic field $\mathbf{H}_{\text{eff}}$ is equal to the variational derivative of the magnetic crystal energy E with respect to the vector $\mathbf{M}$: $\mathbf{H}_{\text{eff}} = -\delta E / \delta \mathbf{M}$. The energy E is assumed to be a function of $\mathbf{M}$, its spatial

derivatives, and depends on the external magnetic field $\mathbf{H}$.

In the case of a many-sublattice magnet, an LL equation for the magnetization of an α -sublattice $\mathbf{M}^\alpha$ coincides with Equation (1) after the replacement $\mathbf{M} \rightarrow \mathbf{M}^\alpha$.

Equation (1) for ferromagnets has an integral of motion $M^2 = M_0 = \text{constant}$ and is consistent with the assumption that the $\mathbf{M}$ -vector length in a ferromagnet is its equilibrium parameter. In the ground state, the quantity M_0 is equal to a so-called spontaneous magnetization $M_0 = 2\mu_0 S / a^3$, where S is the atomic spin and a is the interatomic separation. Conservation of the $\mathbf{M}$ -vector length allows one to rewrite the LL equation in angular variables that are convenient for describing the magnetization dynamics in ferromagnets with axial symmetry. Assuming the external magnetic field directed along the anisotropy axis (the z -axis), let us define (Figure 1)

$$\begin{aligned} M_x + iM_y &= M_0 \sin \theta \exp i\psi, \\ M_z &= M_0 \cos \theta. \end{aligned} \quad (2)$$

Then in a dissipationless case ($\gamma = 0$)

$$\begin{aligned} \sin \theta \frac{\partial \theta}{\partial t} &= -\frac{2\mu_0}{\hbar M_0} \frac{\delta E}{\delta \varphi}, \\ \sin \theta \left(\frac{\partial \varphi}{\partial t} - \frac{2\mu_0 H}{\hbar} \right) &= \frac{2\mu_0}{\hbar M_0} \frac{\delta E}{\delta \theta}, \end{aligned} \quad (3)$$

where the magnetic energy E is written as a function of the angular variables.

The magnetic energy E of a ferromagnet includes two parts: the exchange energy E_{ex} and the magnetic anisotropy energy E_a :

$$\begin{aligned} E_{\text{ex}} &= \frac{1}{2} \alpha \int \frac{\partial \mathbf{M}}{\partial x_k} \frac{\partial \mathbf{M}}{\partial x_k} d^3x, \\ E_a &= -\frac{1}{2} \beta_1 \int M_x^2 d^3x - \frac{1}{2} \beta_3 \int M_z^2 d^3x, \end{aligned} \quad (4)$$

where α is the nonuniform exchange energy constant and β_1 and β_3 are uniaxial anisotropy constants. (When all $\beta = 0$, we have an isotropic ferromagnet; when $\beta_1 = 0$, we have a uniaxial ferromagnet, the easy-axis anisotropy corresponds to $\beta = \beta_3 > 0$ and easy-plane anisotropy to $\beta < 0$; and when $\beta_1 \neq 0$ and $\beta_3 \neq 0$, we have biaxial anisotropy.)

Equations (3) for easy-axis ferromagnets can be written in the form

$$\begin{aligned} l_0^2 \Delta \theta - (1 + l_0^2 (\nabla \varphi)^2) \sin \theta \cos \theta \\ + \frac{1}{\omega_0} \left(\frac{\partial \varphi}{\partial t} - \omega_H \right) \sin \theta = 0, \end{aligned} \quad (5)$$

$$l_0^2 \operatorname{div}(\sin^2 \theta \nabla \varphi) - \frac{1}{\omega_0} \frac{\partial \theta}{\partial t} \sin \theta = 0, \quad (6)$$

Figure 1. The angular variables for the magnetization M .

where $\Delta = \nabla^2$ is the Laplacian, l_0 is the magnetic length ($l_0^2 = \alpha/\beta$), ω is the homogeneous ferromagnetic resonance frequency ($\hbar\omega_0 = 2\mu_0\beta M_0$), and $\omega_H = 2\mu_0 H/\hbar$ is the spin magnetic frequency.

Equations (5) and (6) have two additive integrals of motion, namely, the total momentum of the magnetization field $\mathbf{P}$ and z -component (projection) of the total magnetic moment written after normalization as a number of spin deviations N in the excited state of the magnet:

$$P = -\frac{\hbar M_0}{2\mu_0} \int (1 - \cos \theta) \nabla \varphi \, d^3x, \quad (7)$$

$$N = \frac{M_0}{2\mu_0} \int (1 - \cos \theta) \, d^3x.$$

In a slightly excited state of ferromagnets ($\theta = \theta_0 = \text{constant}$, $\theta_0 \ll 1$, $\psi = \omega t - \mathbf{k}\mathbf{r}$) the magnetization dynamics is equivalent to a set of precessional spin waves that are solutions of linearized Equations (5), (6) with the following dispersion relation:

$$\omega(\mathbf{k}) = \omega_0 + \omega_H + (l_0 k)^2. \quad (8)$$

The simplest static solution of Equations (5), (6) is a domain wall (Figure 2c)

$$\sin \theta = \text{sech}[(x - x_0)/l_0], \quad (9)$$

separating two semispace ferromagnet domains at $x < x_0$ and $x > x_0$. Equation (9) presents a topological solution of the LL equation.

Interesting nontopological soliton solutions of Equations (5) and (6) are two-parametric dynamic magnetic solitons. Magnetic solitons of a general type are given by the following solutions

$$\theta = \theta(\mathbf{r} - \mathbf{V}t), \quad \varphi = (\omega + \omega_H)t + \psi(\mathbf{r} - \mathbf{V}t), \quad (10)$$

where the function θ vanishes at infinity ($\theta = 0$ for $r = \infty$) and $\nabla\psi$ is limited for $r = \infty$, $\mathbf{V}$ is the translational velocity of the soliton, and $\omega + \omega_H$ is the precessional frequency of the magnetization vector in the frame of reference moving along with the soliton. Typical diagrams for the function θ in the 1-d case are

Figure 2. Magnetization distribution in (a) a low-amplitude soliton, (b) a magnetic soliton for small values V and ω , (c) a domain wall.

presented in Figure 2. There are the following Hamilton equations for a dynamic soliton (Kosevich et al., 1977):

$$\mathbf{V} = \left(\frac{\partial E}{\partial \mathbf{P}} \right)_N, \quad \hbar\omega = \left(\frac{\partial E}{\partial N} \right)_P. \quad (11)$$

The 1-dimensional version of Equations (5) and (6) is a totally integrable nonlinear equation in both isotropic (Lakshmanan, 1977; Takhtajan, 1977) and easy-axial (Borovik, 1978) cases and possesses a set of multiple-soliton solutions. The total integrability of 1-d LL equations in the case of biaxial anisotropy was proved by Sklyanin (1979).

If θ is small enough, the 1-d version of Equations (5) and (6) can be reduced to the nonlinear Schrödinger (NLS) equation for the complex function $\psi = M_x + iM_y$ (Volzhan et al., 1976)

$$i \frac{\partial \psi}{\partial t} - l_0^2 \frac{\partial^2 \psi}{\partial x^2} + (1 + h)\psi - \frac{1}{2M_0} |\psi|^2 \psi = 0, \quad (12)$$

which is used for description of small amplitude long-wave excitations in one-dimensional easy-axial ferromagnets.

Another limiting case arises for a ferromagnet with the biaxial anisotropy ($\beta_1 < 0$ and $\beta_3 > 0$) under the condition $\varepsilon = -\beta_1/\beta_3 \gg 1$. Then the plane YOZ plays easy-plane, the magnetization vector lies nearly in this plane, $\chi = \pi/2 - \theta \ll 1$, and the LL equation is transformed to the following equations:

$$l_0^2 \frac{\partial^2 \phi}{\partial x^2} - \frac{1}{\varepsilon \omega_0} \frac{\partial^2 \phi}{\partial t^2} + \sin \phi \cos \phi = 0,$$

$$\omega_0 \chi = -\frac{1}{\varepsilon} \frac{\partial \phi}{\partial t}, \quad (13)$$

where the new angle variable ϕ is introduced with the equation $M_x + iM_y = M_0 \cos \chi \exp i\phi$.

At present, the LL equation is widely used for models of nonlinear macroscopic dynamic phenomena such as spin waves in inhomogeneous or spatially limited magnets, magnetostatic vibrations, magnetization dynamics, interaction of magnetically ordered media with electromagnetic and elastic waves, nonlinear magnetization waves, and magnetic solitons.

LANGMUIR-BLODGETT FILMS

The calming effect of oil on water has been known for centuries, and one early account of the phenomenon, on clay tablets, dates from the 18th century BCE in Babylonia. In 1879, a provisional British patent was filed by John Shields, the proprietor of a Scottish linen mill, for a simple device for spreading oil from valves in undersea pipes to calm the waves at the entrances to harbors. However, the first account of an experiment to investigate this effect was probably that of Benjamin Franklin in 1773, who wrote the following in a letter to a colleague.

At length being at Clapham, where there is on the common a large pond, which I observed one day to be very rough with the wind, I fetched out a cruet of oil, and dropped a little of it on the water, and there the oil, though not more than a teaspoonful, produced an instant calm over a space several yards square, which spread amazingly, and extended itself gradually till it reached the lee side, making all that quarter of the pond, perhaps half an acre as smooth as a looking-glass.

A quick calculation reveals that Franklin's oil film was 1–2 nm thick—about the same as the size of an oil molecule, but this implication was not realized for many years. Although Lord Rayleigh was the first to propose that such films were only one molecule in thickness, he was not able to make a direct measurement to confirm this. The simple equipment for monolayer studies, now known as a Langmuir trough, was first introduced by Agnes Pockels. In a letter to Lord Rayleigh in 1891, she described the methods that formed the foundation of monolayer research.

Irving Langmuir provided most of the early scientific evidence for the existence of monolayer films. In 1917, he published a substantial paper outlining the properties of such films on a water surface. Some years later, Katharine Blodgett, working with Langmuir at the General Electric Company Research Laboratories in Schenectady, New York, devised a method for transferring the floating monolayers onto solid surfaces. The resulting films now bear the name of these two researchers.

Until the outbreak of World War II, research into the properties of monolayer films flourished, the work being undertaken mainly by surface chemists. However, few uses were found for monolayer and multilayer structures so activity in the area declined. Interest was rekindled in the 1970s following some stimulating experiments on energy transfer in multilayer systems by Hans Kuhn working in Germany. At about this time, organic chemists became aware of the limited range of monolayer forming materials that was available. Novel electroactive compounds were synthesized (dyes, semiconductors, polymers), and a new series of investigations began. This coincided with the birth of molecular electronics, a new interdisciplinary research

activity focused on the exploitation of organic materials in electronic and optoelectronic devices. Related thin film technologies, such as self-assembly and layer-by-layer electrostatic deposition, were also developed. By the end of the 20th century, a number of organic thin film deposition technologies and materials, suitable for fabricating organic molecular architectures, was available. The era of molecular nanotechnology had begun.

Materials that produce organized monomolecular layers on the surface of water invariably consist of molecules possessing both water-attracting (hydrophilic) and water-repelling (hydrophobic) chemical groups. Such organic compounds are called amphiphiles. One of the simplest materials suitable for forming such a monomolecular layer is stearic acid, $C_{17}H_{35}COOH$. The molecule consists essentially of 16 CH_2 groups forming a long hydrocarbon chain; one end of the chain terminates in a hydrophilic carboxylic acid $COOH$ group.

Langmuir-Blodgett (LB) films are prepared by first depositing a small quantity of the amphiphilic material, dissolved in a volatile solvent such as chloroform, on the surface of carefully purified water (subphase). When the solvent has evaporated, the organic molecules may be compressed to form a floating two-dimensional solid. The hydrophilic and hydrophobic terminations of the molecules ensure that the individual molecules are aligned in the same way during this process. During compression the monolayer undergoes a number of phase transformations. The different phases are almost analogues of three-dimensional gases, liquids and solids. The phase changes may be readily identified by monitoring the surface pressure Π as a function of the area occupied by the film. This is the two-dimensional equivalent of the pressure versus volume isotherm for a gas/liquid/solid. Figure 1 shows such a plot for a hypothetical long-chain organic monolayer material (e.g., a long-chain fatty acid).

In the "gaseous" state (G in Figure 1), the molecules are far enough apart on the water surface that they exert little force on one another. As the surface area of

the monolayer is reduced, the hydrocarbon chains will begin to interact. The "liquid" state that is formed is generally called the expanded monolayer phase (E). The hydrocarbon chains of the molecules in such a film are in a random, rather than a regular orientation, with their polar groups in contact with the subphase. As the molecular area is progressively reduced, condensed (C) phases may appear. There may be more than one of these, and the emergence of each condensed phase can be accompanied by constant pressure regions in the isotherm, as observed in the cases of a gas condensing to a liquid and a liquid solidifying. These regions will be associated with enthalpy changes in the monolayer. In the condensed monolayer states, the molecules are closely packed and are oriented with their hydrocarbon chains pointing away from the water surface. The area per molecule in such a state will be similar to the cross-sectional area of the hydrocarbon chain, that is, $\approx 0.19 \text{ nm}^2 \text{ molecule}^{-1}$.

The LB technique requires that the surface pressure and temperature of the floating monolayer are controlled so that the organic film is in a condensed and stable state. Figure 2 shows the commonest form of LB deposition. The substrate is hydrophilic and the first layer is transferred, like a carpet, as the substrate is raised vertically through the water. Subsequently, a monolayer is deposited on each traversal of the monolayer/air interface. As shown, these stack in a head-to-head and tail-to-tail pattern; this

Figure 1. Surface pressure versus area per molecule for a long-chain organic compound. (The surface pressure and area are in arbitrary units (a.u.).)

Figure 2. Y-type Langmuir-Blodgett film deposition.

deposition mode is called Y-type. Although this is the most frequently encountered situation, instances in which the monolayer is transferred to the substrate as it is being inserted into the subphase, or only as it is being removed, are often observed. These deposition modes are called X-type (monolayer transfer on the downstroke only) and Z-type (transfer on the upstroke only).

It is also possible to build up thin film architectures containing more than one type of monomolecular layer. In the simplest case, alternate-layer films may be produced by raising the substrate through a monolayer of one material (consisting of molecules of compound A, say) and then lowering the substrate through a monolayer of a second substance (compound B). An asymmetric multilayer structure consisting of ABABAB... layers is produced. This control over the molecular architecture permits the fabrication of organic superlattices with precisely defined symmetry properties. Such molecular assemblies can exhibit pyroelectric, piezoelectric, and second-order nonlinear optical phenomena.

Film transfer is characterized by measurement of the deposition ratio, τ (also called the transfer ratio). This is the decrease in the area occupied by the monolayer (held at constant pressure) on the water surface divided by the coated area of the solid substrate, that is,

$$\tau = A_L/A_S, \quad (1)$$

where A_L is the area occupied by the monolayer on the water surface and A_S is the coated area of the solid substrate. Transfer ratios significantly outside the range 0.95–1.05 suggest poor film homogeneity.

A schematic diagram of one experimental arrangement to deposit LB films is shown in Figure 3, together with a photograph of the equipment. The Langmuir trough is made from PTFE (polytetrafluoroethylene) and a working area is defined by a PTFE-coated glass fiber barrier, which can be moved using a low-g geared electric motor. The barrier motor is coupled to a sensitive electronic balance, which continuously monitors, via a sensing plate (Wilhelmy plate), the surface pressure of the monolayer. Using a feedback arrangement, this pressure can be maintained at a predetermined value. The physical dimensions of the Langmuir trough arrangement are not critical (the system in the photograph is approximately 30 cm in length) and are governed by the size of the substrate used.

Many analytical techniques, such as X-ray and electron diffraction, and infrared spectroscopy may be used to study the orientation of molecules in an LB assembly. Figure 4 shows an 9 nm $\times$ 9 nm atomic force micrograph of the surface of a 12-layer fatty acid LB film. The lighter parts of the image relate to the higher part of the surface and the darker regions correspond to deeper down. Lines of individual molecules are evident at the magnification shown, confirming the

Figure 3. Langmuir-Blodgett trough (courtesy Molecular Photonics).

Figure 4. An atomic force micrograph of a fatty acid LB film.

highly ordered arrangement of organic molecules in the LB film.

The vertical dipping LB process is not the only way to transfer a floating molecular film to a solid substrate or to build-up multilayer films. Other methods are based on touching one edge of a hydrophilic substrate with the monolayer-covered subphase or lowering the substrate horizontally so that it contacts the hydrophobic ends of the floating molecules. Chemical means, for example, self-assembly of a thiol group onto a gold-coated substrate, can also be used to deposit monolayer organic films. In contrast, electrostatic layer-by-layer assembly relies on the forces between positively and negatively charged polyelectrolytes.

The earliest technical application of organic monolayer films is believed to be the Japanese printing art called *sumi-nagashi*. The dye comprising a suspension

of submicron particles and protein molecules is first spread on the surface of water; the application of gelatin to the uniform layer converts the film into a patchwork of colorless and dark domains. These distinctive patterns can then be transferred by lowering a sheet of paper onto the water surface.

There are, of course, many methods available to deposit thin films of organic materials, including: thermal evaporation, sputtering, spaying, painting, dip- and spin-coating, electrodeposition, and molecular beam epitaxy. However, the LB technique is one of the few thin film technologies that actually permits the manipulation of materials at the molecular level. It should, therefore, be appropriate for exploitation by workers in nanotechnology wishing to fabricate interesting material architectures (bottom-up approach to nanotechnology) or to build up novel electronic device structures.

A range of possible applications for LB and related films is evident from the literature. Many of the ideas exploit the physical and chemical properties of the ultra-thin films to provide surface coatings with particular catalytic, adhesive, or mechanical properties (e.g., low friction). The availability of new polymeric amphiphiles has led to an interest in semi-permeable membranes. The extreme thinness of monolayer and multilayer films could provide key benefits in a variety of chemical sensing structures. For gas sensing, adequate sensitivities to some important gases and vapors have already been achieved using a variety of transduction techniques (chemiresistor, surface plasmon resonance, acousto-electric coupling, and so on).

For commercial exploitation, it is imperative to establish those areas in which LB films offer significant advantages over layers produced by other (and perhaps cheaper) means. In the case of second-order nonlinear optics, the LB method offers a means of aligning the molecules in a film of micrometer dimensions. Materials with high second-order hyperpolarizabilities (for example, leading to significant second-harmonic generation) already exist. Further work is needed on the development of practical electro-optic structures with attention to important considerations such as encapsulation and device degradation.

It is also interesting to note that a large number of biological materials form monolayers on a water surface. Chlorophyll a, the green pigment in higher plants; vitamins A, E and K; and cholesterol are all examples. Monomolecular films resemble naturally occurring biological membranes, which are based on a bilayer arrangement of long-chain phospholipid molecules. The LB technique might, therefore, be used as a means to fabricate artificial structures that emulate certain biological functions, such as photosynthesis, molecular recognition, or parallel information processing.

LASERS

An acronym for Light Amplification by Stimulated Emission of Radiation, a laser involves interaction of light with matter at the molecular, atomic, or nuclear levels and requires a quantum mechanical description of both light and matter. According to quantum mechanics, when an electron decays from an excited level E_+ to a lower energy level $E_- < E_+$, a photon of energy $E_+ - E_-$ and frequency $\nu = (E_+ - E_-)/h$ is emitted, where $h \doteq 6.672 \times 10^{-34}$ J s is Planck's constant.

The decay of electrons from excited states and the consequent emission of light is stimulated by the interaction of photons (of the appropriate energy) with the electrons (Einstein's stimulated emission). The emitted photons can then interact with excited electrons to produce a cascade of coherent photons, making up the familiar laser beam.

For a laser to work, three basic elements are required:

- (i) an energy level structure for the electrons (e.g., atomic or molecular fluids (gases or liquids), solids (crystals or glasses), or semiconducting junctions);
- (ii) a pumping mechanism (such as electrical current or light) to populate the upper energy level; and
- (iii) an optical cavity to partially confine the photons, enhancing their probability of interacting with the excited electrons.

The most common laser structures are Fabry-Perot cavities (where light is confined between two opposite mirrors) and ring lasers (in which light travels in one direction along the border of a rectangle with mirrors appropriately oriented in the corners) (Siegman, 1986) (see Figure 1). Industrial lasers are normally of Fabry-Perot type while ring lasers are often preferred in research laboratories.

The simplest laser model, describing only the first two required elements, consists of the laser rate equations, which model a laser medium in terms of the number of photons (proportional to the light

Figure 1. Ring and Fabry-Perot laser cavities.

intensity, I) and the number of excited electrons inside the laser cavity. Because the photon field can induce upward as well as downward transitions, the excited electrons are measured by the population inversion $N \equiv N_+ - N_-$, where N_+ (N_-) denotes the number of electrons in the upper (lower) level.

The photon population (I) is diminished due to the laser output as well as through other losses at a rate εI . Stimulated emission decreases the population inversion and increases the photon number at a rate αN_+ , while absorption of photons produce the inverse effect at a rate αN_- . (The equivalence between emission and absorption rate per electron is a quantum mechanical result. Note that for each photon emitted, the population inversion decreases by two as N_+ decreases by one, while N_- increases by the same amount.) Excited electronic states (N_+) are also produced by the pumping mechanism at a rate $A/2$ (which may be a function of time) and diminished by nonradiative processes at a rate $\gamma(N - N_{eq})$ (where N_{eq} , a negative number, derives from the population inversion at thermal equilibrium). A simple formulation of the laser rate equations is, therefore,

$$\frac{dI}{dt} = [-\varepsilon + \alpha N] I, \quad (1)$$

$$\frac{dN}{dt} = (A + \gamma N_{eq}) - \gamma N - 2\alpha N I. \quad (2)$$

These laser rate equations have either one or two fixed points corresponding to steady operation of the laser. The laser-off state with $I = 0$ and $N = N_0 = A/\gamma + N_{eq}$ is always present. The stability of the laser-off solution depends on the sign of $\lambda = -\varepsilon + \alpha N_0$. If this quantity is positive, small disturbances such as those produced by spontaneous emission are amplified and laser action develops. If $\lambda < 0$, disturbances die out, hence $\lambda = 0$ implies a threshold value for the pumping of $A = \gamma(\varepsilon/\alpha - N_{eq})$. Steady operation of a laser above threshold is represented by the laser-on state $N = N_1 = \varepsilon/\alpha$ and $I = (\gamma/2\alpha)(N_0 - N_1)/N_1$.

These equations correspond to birth and death processes of photons and electrons that resemble those of predator and prey species in population dynamics. This analogy is somewhat tenuous, however, because quantum theory does not allow a photon or electron to be localized in time and energy simultaneously. Hence, the statistical description of a laser requires of entrained electron-photon states and the descriptions of quantum jump processes (Carmichael, 1999).

A more detailed set of equations is obtained by considering a laser operating in a single longitudinal cavity mode (i.e., having a fixed spatial pattern within the optical cavity). With a simple quantum mechanical model for electron energy levels and a classical description of the electromagnetic field (i.e., a large number of photons), the dynamics of the laser are described by Maxwell-Bloch equations, which involve complex amplitudes of the electric and polarization fields in addition to the population inversion (N) (Narducci & Abraham, 1988).

An aim of laser design has long been to achieve lasers of higher photon energies. While ultraviolet lasers were developed early, X-ray lasers have only recently been demonstrated (Rocca, 1999), and gamma-ray lasers are not yet realized.

Lasers can be classified in various ways according to their dynamics, the active media, the optical cavity, the pumping scheme, optical frequency, among others. Considering the active media, lasers can be grouped as follows.

Solid State Lasers

Solid state lasers, such as the ruby laser (the first laser, announced in 1960), which has a three-level pumping scheme for which Cr^{3+} impurities are essential, require a high-energy source for pumping and operate intermittently. In contrast, Nd-YAG (neodymium-doped yttrium aluminum garnet) and Nd-glass lasers are based in a four-level scheme, operate under moderate pump power, and display different dynamical regimes. Ruby and Nd-YAG lasers represent the two basic pumping schemes for solid state lasers.

In the three-level pumping scheme, the light emitting transition has the ground state as the final state, while in the four-level scheme the state reached by the electron after the transition is an excited state.

There are a large number of solid state lasers operating at different frequencies, each with particular features. Many of them employ a host crystal (or glass) doped with an impurity such as $\text{Al}_2\text{O}_3(\text{Cr}^{3+})$, $\text{Y}_2\text{O}_3(\text{Eu}^{3+})$, $\text{Gd}_2\text{O}_3(\text{Nd}^{3+})$, or $\text{BaF}_2(\text{U}^{3+})$.

Gas Lasers

Several active media fall in this category: helium-neon, argon, and the powerful CO_2 are among the best-known representatives. The standard method for the excitation

of the molecular states is an electric discharge in the gaseous medium where collisions between excited ions provide the pumping mechanism. However, optical pumping and other pumping mechanisms have been demonstrated for some gas lasers.

Gas lasers can be operated in continuous wave and pulsed modes and are particularly important at the low-frequency (infrared) region of the electromagnetic spectrum. Other members of this class include H_2O , HCN , CH_2I , and HF lasers.

Liquid Lasers

The best-known representatives are dye lasers, where a stream of organic liquid is excited using visible or ultraviolet radiation from a flash lamp or a laser beam. The pumping mechanism involves radiative fluorescence at a lower frequency than that of the pumping source, a mechanism known as Stokes-shift.

Other lasers in this class are based on solutions of rare earth elements. In contrast with gas and solid state lasers, dye lasers usually operate in cavities with relatively high losses.

Semiconductor Lasers

Because of their small size, semiconductor lasers play an important role in electronic applications. While earlier lasers were built as semiconductor diodes using p-n junctions as in GaAs diodes (or PbS, PbSe, PbTe, SnTe, InSb, etc.) new generations of lasers, such as the Vertical Cavity Surface Emitting Laser (VCSEL) are produced modifying semiconductor surfaces and reducing the size and power requirements of the laser significantly. Semiconductor lasers are pumped by direct electrical current using the band structure of the semiconductor and electron-hole recombination to produce the photons.

Nuclear Magnetic Resonance

The unique NMR laser relies on the (permanent) magnetic momentum of nuclei, which are pumped using a radio-frequency field. Optical pumping has also been demonstrated recently.

For gas lasers, some liquid lasers, and solid state lasers, the lasing threshold is reached only with high reflectivity mirrors minimizing the cavity losses (small ϵ). Such lasers operate just above threshold in a mode that is almost resonant with the frequency of the atomic transition and can be viewed as weakly nonlinear systems. Wide cavities, higher pumping levels, feedback, and other effects can induce multimode dynamics, where several empty cavity modes are required for the spatial description of the dynamics.

When laser devices are based on lossy electromagnetic cavities, as in dye and semiconductor lasers,

the relation between cavity modes and monochromatic states (or solutions) is obscured. Nevertheless, these are also called multimode lasers when a description of the spatial extension is required.

Despite the diversity of active media, pumping mechanisms, and lasing frequencies, the dynamics of lasers are often rather similar, the main differences accounted for by different parameter values in Maxwell-Bloch type equations. The dynamics of most lasers are described by simple dynamical attractors (fixed points) under constant pumping. There are, however, situations in which complex behavior emerges; thus, optical reinjection of the emitted light can destabilize a laser. Such a process might occur when the laser is coupled to optic fibers in a communication system. The Lang-Kobayashi equations (Lang & Kobayashi, 1980) (a modification of the rate equations including a delayed field) describe this situation for very small amounts of reinjected signal. In the case of semiconductor lasers, even small amounts of optical feedback require a spatial description of the laser cavity (multimode operation) (Huyet et al., 1998; Duarte & Solari, 1998). Attempts to control, or mode lock, a (usually powerful) slave laser with a (usually weak) master laser also generate a rich dynamical spectrum at the unlocking transition (Zimmermann et al., 2001).

LATTICE GAS METHODS

When one is interested in studying the dynamical behavior of fluid systems starting at the microscopic

level, it is logical to begin with a molecular dynamics description of the interactions between the constituting particles. This is often a formidable task, as the fluid evolves into a nonlinear regime where chaos, turbulence, or reactive processes take place. But one may question whether a realistic description of the microscopic dynamics is necessary to gain insight on the underlying mechanisms of large-scale nonlinear phenomena. Around 1985, a considerable simplification was introduced (Frisch et al., 1986). These pioneering studies established (theoretically and computationally) the feasibility of simulating fluid dynamics via a microscopic approach based on a new paradigm. A virtual simplified micro-world is constructed as an automaton universe, based not on a realistic description of interacting particles but merely on the laws of symmetry and of invariance of macroscopic physics.

Suppose we implement point-like particles on a regular lattice where they move from node to node at each time step and undergo collisions when their trajectories meet at the same node. As the system evolves, we observe its collective dynamics by looking at the lattice from a distance. A remarkable fact is that—if the collisions occur according to some simple logical rules (satisfying fundamental conservations) and if the lattice has the proper symmetry—this “lattice gas automaton” (LGA) shows global behavior very similar to that of a real fluid. So we can infer that despite its simplicity at the microscopic scale, the LGA should contain the essential features that are responsible for the emergence of complex behavior and, thereby, can help us understand the basic mechanisms involved.

An LGA consists of a set of particles moving on a regular d -dimensional lattice $\mathcal{L}$ at discrete time steps, $t = n\Delta t$, with n an integer. The lattice is composed of V nodes, labeled by the d -dimensional position vectors $\mathbf{r} \in \mathcal{L}$. Associated to each node are b channels, labeled by indices $i, j, \dots$, running from 1 to b . At a given time t , a channel can be either occupied by one particle or empty, so that the occupation variable $n_i(\mathbf{r}, t) = 1$ or 0. When channel i at node $\mathbf{r}$ is occupied, then the particle at the specified node $\mathbf{r}$ has velocity $\mathbf{c}_i$. The set of allowed velocities is such that the condition $\mathbf{r} + \mathbf{c}_i \Delta t \in \mathcal{L}$ is fulfilled. The “exclusion principle” requirement that the maximum occupation be of one particle per channel allows for a representation of the automaton configuration in terms of a set of bits $\{n_i(\mathbf{r}, t)\}; \mathbf{r} \in \mathcal{L}, i = \{1, b\}$. The evolution rules are thus simply logical operations over sets of bits.

The time evolution of the automaton takes place in two stages: propagation and collision. In the propagation phase, particles are moved according to their velocity vector, and in the (local) collision phase, the particles occupying a given node are redistributed among the channels associated to that node. So the

microscopic evolution equation of the LGA reads

$$\begin{aligned} n_i(\mathbf{r} + \mathbf{c}_i \Delta t, t + \Delta t) \\ = n_i(\mathbf{r}, t) + \Delta_i(\{n_j(\mathbf{r}, t)\}), \end{aligned} \quad (1)$$

where $\Delta_i(\{n_j\})$ represents the collision term that depends on all channel occupations at node $\mathbf{r}$. By performing an ensemble average (denoted by angular brackets) over an arbitrary distribution of initial occupations, one obtains a hierarchy of coupled equations for the successive n -body distribution functions. This hierarchy can be truncated to yield the lattice Boltzmann equation for the single particle distribution function $f_i(\mathbf{r}, t) = \langle n_i(\mathbf{r}, t) \rangle$:

$$\begin{aligned} f_i(\mathbf{r} + \mathbf{c}_i \Delta t, t + \Delta t) - f_i(\mathbf{r}, t) \\ = \Delta_i^{\text{Boltz}}(\{f_j(\mathbf{r}, t)\}). \end{aligned} \quad (2)$$

The left-hand side is recognized as the discrete version of the left-hand side of the classical Boltzmann equation for continuous systems, and the right-hand side denotes the collision term, where the precollisional uncorrelated state *ansatz* has been used to factorize the b -particle distribution function.

The lattice Boltzmann equation (2) is one of the most important results in LGA theory. It can be used as the starting point for the derivation (via multi-scale analysis) of the macroscopic equations describing the long wavelength behavior of the lattice gas. The LGA macroscopic equations are found to exhibit the same structure as the classical hydrodynamic equations, and under the incompressibility condition, one retrieves the Navier–Stokes equations for nonthermal fluids. Another important feature of the lattice Boltzmann equation is that it can be used as an efficient and powerful simulation algorithm. In practice, one usually prefers to use a simplified equation where the collision term is approximated by a single relaxation time process inspired by the Bhatnagar–Gross–Krook model, known in its lattice version as the LBGK equation:

$$\begin{aligned} f_i(\mathbf{r} + \mathbf{c}_i \Delta t, t + \Delta t) - f_i(\mathbf{r}, t) \\ = -\frac{1}{\tau} \left[f_i(\mathbf{r}, t) - f_i^{\text{eq}}(\mathbf{r}, t) \right], \end{aligned} \quad (3)$$

where the right-hand side is proportional to the deviation from the local equilibrium distribution function.

There is a wealth of applications of the lattice gas methods that have established their validity and their usefulness. LGA simulations, based on Equation (1), are most valuable for fundamental problems in statistical mechanics, such as the study of fluctuation correlations in equilibrium and non-equilibrium systems (Rivet & Boon, 2001; Rothman & Zaleski, 1997). As an example, Figure 1 shows

Figure 1. Lattice gas simulation of the Kolmogorov flow: the tracer trajectories reflect the topology of the *ABC* flow in the regime beyond the critical Reynolds number ($Re = 2.5 \times Re_c$).

Figure 2. Lattice Boltzmann (LBGK) simulation of viscous fingering in miscible fluids (upper panel) showing the interface sharpening effect of a reactive process between the two fluids (lower panel).

the trajectories of tracer particles suspended in a Kolmogorov flow (above the critical Reynolds number) produced by a lattice gas automaton and from where turbulent diffusion was analyzed (Boon et al., 2000).

Simulations of more direct practical interest, such as, for instance, profile optimization in car design or turbulent drag problems, are most efficiently treated with the lattice Boltzmann method, in particular using the LBGK model. The example given in Figure 2 illustrates the method for the study of viscous fingering in Hele-Shaw geometry, showing the effect of reactivity between the two fluids as a determinant factor in the dynamics of the moving interface (Grosfils & Boon, 2002).

Applications of the LGA approach and of the lattice Boltzmann equation cover a wide variety of theoretical and practical problems ranging from the dynamics of thermal fluctuations and quantum lattice gas automata to multi-phase flow, complex fluids, reactive systems, and inhomogeneous turbulence.

LÉVY FLIGHTS

In 1937, the French mathematician Paul Lévy (1886–1971) introduced statistical descriptions of motion that

extend beyond the more traditional Brownian motion discovered over one hundred years earlier. A diverse range of both natural and artificial phenomena is now being described in terms of Lévy statistics, from the flight of an albatross across the Antarctic skies to the trajectories followed by the abstract painter Jackson Pollock as he constructed his famous drip paintings.

In 1828, Robert Brown published his studies of the random motion of soot particles in a dish of water as they were buffeted from random directions by the thermal motion of water molecules. In 1905, Albert Einstein provided a theoretical basis for this diffusion process. A particle's Brownian motion is pictured as a sequence of jumps. For a single jump, the probability dependence on jump size x has a Gaussian distribution. A consequence of Gaussian statistics is that the size distribution for N jumps is also described by a Gaussian.

Paul Lévy generalized beyond Brownian motion by considering other distributions for which one jump and N jumps share the same mathematical form. These Lévy distributions decrease according to the power law $1/x^{1+\gamma}$ for large x values, where γ lies between 0 and 2. Compared with Gaussian distributions, Lévy distributions do not fall off as rapidly at long distances. For Brownian motion, each jump is usually small and the variance of the distribution, $\langle x^2 \rangle$, is finite. For Lévy motion, however, the small jumps are interspersed with longer jumps, or "flights," causing the variance of the distribution to diverge. As a consequence, Lévy jumps do not have a characteristic length scale.

This scale invariance is a signature of fractal patterns. Indeed, Lévy's initial question of "When does the whole look like its parts?" addresses the fractal property of self-similarity. An important parameter for assessing the scaling relationship of fractal patterns is dimension. What, then, is the dimension of the pattern traced out by Lévy motion? The short jumps making up Brownian motion build a clustered pattern that is so dense that area is a more appropriate measure than length—the pattern is actually two-dimensional. In contrast, although the short jumps of Lévy motion produce a clustering, the longer, less frequent jumps initiate new clusters. These clusters form a self-similar pattern with a dimension of less than two. Fractional dimensions are an exotic property of fractals.

Today, Lévy motion is as widely explored in nonlinear, chaotic, turbulent, and fractal systems as Brownian motion is in simpler systems. Following Mandelbrot's research in the 1970s demonstrating the prevalence of fractal patterns in nature, an increasing number of natural phenomena have been described using Lévy statistics (Mandelbrot, 1982). Lévy distributions are also having an impact on artificial systems. A recent example concerns nano-scale electronic devices in which chaotic electron trajectories produce Lévy statistics in the electrical conduction

properties (Micolich et al., 2001). Other examples include diffusion in Josephson junctions (Geisel et al., 1985) and at liquid-solid interfaces (Stapf et al., 1995).

It is even possible to picture relatively simple systems in which both Brownian and Lévy motion appear and a transition between the two can be induced. Consider, for example, dropping tracer particles into a container of liquid. This, of course, is Brown's original experiment. In 1993, Harry Swinney extended this experiment by considering a rotating container of liquid shaped like a washer. As turbulence set in, vortices appeared in the liquid and Swinney's group showed that the tracer particles followed Lévy flights between the vortices with $\gamma = 1.3$ (Solomon et al., 1993).

In addition to spatial distributions, Lévy statistics can also be applied to distributions measured as a function of time. A famous example is the dripping faucet (See **Dripping faucet**). In 1995, Thadeu Penna's group showed that the fluctuations in the time intervals between drips follow a Lévy distribution with $\gamma = 1.66-1.85$. A significant appeal of this result lies in a comparison with earlier medical work by Ary Goldberger's group showing that fluctuations in the human heart beat follow $\gamma = 1.7$ (Goldberger, 1996). This prompted Penna to ask, "Is the heart a dripping faucet?"

Goldberger suggested that the Lévy statistics describing the human heart arise from nonlinear processes that regulate the human nervous system. He has since extended his research of the fractal dynamics of physiology to other examples of involuntary behavior. This includes studies of the human gait that show that fluctuations in stride intervals display fractal variations (Hausdorff et al., 1996). Fractal variations might therefore be a general signature of healthy human behavior, exhibited whenever conscious control is not involved.

It is interesting to consider this speculation within the context of the results of the British Antarctic Survey in 1996, which showed that albatrosses follow Lévy flights. Other species of animals, such as ants and bees, also follow Lévy flights when foraging for food. Due to the diverging variance of the flight distribution, Lévy trajectories represent an efficient way of covering large regions of space, especially when compared with Brownian motion. Significantly, these animal behavioral patterns represent yet another example of Lévy behavior generated by actions that are devoid of intellectual deliberation.

This relationship between unconscious actions and Lévy statistics has even touched on human creativity. In particular, the Surrealist art movement developed a technique called automatic painting, in which artists painted with such speed that any conscious involvement was thought to be eliminated. Jackson Pollock adopted this approach during the 1940-1950s when he dripped paint onto large horizontal canvases (see *Autumn Rhythm*, Figure 1). Remarkably, his paintings are fractal

Figure 1. *Autumn Rhythm (Number 30)*, by Jackson Pollock, 1950. © 2003 The Pollock-Krasner Foundation / Artists Rights Society (ARS) New York. Courtesy The Metropolitan Museum of Art, George A. Hearn Fund, 1957. (57.92)

and his motions have been described in terms of Lévy flights (Taylor et al., 1999). This work triggered visual perception tests that identified an aesthetic preference for fractal patterns with dimensions between 1.3 and 1.5 (Taylor, 2001).

Lévy distributions represent a truly interdisciplinary phenomenon that will continue to be useful as novel artificial and natural systems are explored.

LIE ALGEBRAS AND LIE GROUPS

Lie groups were introduced by the 19th century Norwegian mathematician Sophus Lie through his studies in geometry and integration methods for differential equations (Hawkins, 1999). Further developments by W. Killing, É. Cartan and H. Weyl established Lie's theory as a cornerstone of mathematics and its physical applications. General references include Duistermaat & Kolk (1999), Sattinger & Weaver (1986), and Varadarajan (1984).

An r parameter Lie group is defined as an r -dimensional manifold that is also a group with smooth multiplication and inversion maps. A key example is the $r = n^2$ -dimensional general linear group $GL(n)$ of (either real or complex) $n \times n$ nonsingular matrices, $\det A \neq 0$, under matrix multiplication. Most Lie groups can be realized as matrix groups, that is, subgroups of $GL(n)$. Important examples include the

- special linear group $SL(n) \subset GL(n)$ with $\det A = 1$, and $r = n^2 - 1$;
- orthogonal group $O(n) \subset GL(n, \mathbb{R})$ with $A^T A = I$, and $r = n(n - 1)/2$;

- unitary group $U(n) \subset GL(n, \mathbb{C})$ with $A^\dagger A = I$, and $r = n^2$;
- symplectic group $Sp(2n) \subset GL(2n, \mathbb{R})$ with $A^T J A = J = \begin{pmatrix} 0 & -I \\ I & 0 \end{pmatrix}$, and $r = n(2n + 1)$.

A Lie algebra $\mathfrak{g}$ is a vector space equipped with a skew-symmetric, bilinear bracket $[\cdot, \cdot]: \mathfrak{g} \times \mathfrak{g} \rightarrow \mathfrak{g}$ that satisfies the Jacobi identity

$$[u, [v, w]] + [v, [w, u]] + [w, [u, v]] = 0.$$

The Lie algebra $\mathfrak{g}$ of left-invariant vector fields on an r -parameter Lie group G can be identified with the tangent space at the identity, and so $\dim \mathfrak{g} = r$. The Lie algebra $\mathfrak{gl}(n)$ of $GL(n)$ consists of all $n \times n$ matrices under matrix commutator $[A, B] = AB - BA$. A finite-dimensional Lie algebra with basis $v_1, \dots, v_r$ is specified by its structure constants c_{jk}^i , defined by the bracket relations $[v_j, v_k] = \sum_{i=1}^r c_{jk}^i v_i$. Each finite-dimensional Lie algebra corresponds to a unique connected and simply connected Lie group G^* ; any other is obtained by quotienting by a discrete normal subgroup: $G = G^*/N$.

A subspace $\mathfrak{h} \subset \mathfrak{g}$ is a subalgebra if it is closed under the Lie bracket: $[\mathfrak{h}, \mathfrak{h}] \subset \mathfrak{h}$. Lie subalgebras are in one-to-one correspondence with connected Lie subgroups $H \subset G$. The subalgebra is an ideal if $[\mathfrak{g}, \mathfrak{h}] \subset \mathfrak{h}$. A Lie algebra is simple if it contains no nontrivial ideals, and semi-simple if it contains no nontrivial abelian (commutative) ideals. Semi-simple algebras are direct sums of simple algebras. A Lie algebra is solvable if the sequence of subalgebras $\mathfrak{g}^{(0)} = \mathfrak{g}$, $\mathfrak{g}^{(k+1)} = [\mathfrak{g}^{(k)}, \mathfrak{g}^{(k)}]$ eventually terminates with $\mathfrak{g}^{(n)} = \{0\}$. The Levi decomposition says that every Lie algebra is the semi-direct sum of a semi-simple subalgebra and its radical—the maximal solvable ideal.

The Killing–Cartan classification of complex simple Lie algebras contains four infinite families, denoted A_n, B_n, C_n, D_n , corresponding to the simple Lie groups $SL(n+1)$, $O(2n+1)$, $Sp(2n+1)$, $O(2n)$. In addition, there are five exceptional simple Lie groups, G_2, F_4, E_6, E_7, E_8 , of respective dimensions 14, 52, 78, 133, 248. The last plays an important role in modern theoretical physics. Extending the classification to infinite-dimensional simple Lie algebras leads to the Kac–Moody Lie algebras, of importance in integrable systems, theoretical physics, differential geometry, and topology (Kac, 1990).

Lie groups typically arise as symmetry groups of geometric objects or differential equations. A (Lie) group G acts on a manifold M , for example, Euclidean space, provided $m \mapsto g \cdot m$ for $g \in G, m \in M$, defines a sufficiently smooth invertible map that respects the group multiplication. Lie classified all transformation groups acting on one- and two-dimensional real and complex manifolds (Olver, 1995). According to Klein's Erlanger Program, geometric structure is prescribed by

an underlying transformation group; thus, Euclidean, affine, conformal, projective geometries are based on the eponymous Lie groups. If G acts transitively, then $M = G/H$ is a homogeneous space, obtained by quotienting by a closed Lie subgroup. The group orbits—minimal invariant subsets—form a system of submanifolds, and the invariant functions are constant on orbits. The infinitesimal generators of the group action form a Lie algebra $\mathfrak{g}$ of vector fields tangent to the orbits whose flows generate the group action.

A linear action $\rho: G \rightarrow GL(V)$ on a vector space V is known as a representation. Representation theory plays a fundamental role in quantum mechanics since linear symmetries of the Schrödinger equation induce actions on the space of solutions, which decompose into irreducible representations. The structure of atoms, nuclei, and elementary particles is governed by the representations of particular symmetry groups (Hamermesh, 1962). Important special functions, for example, Bessel and hypergeometric, arise as matrix entries of representations of particular Lie groups (Vilenkin & Klimyk, 1991). The representation theory of the orthogonal group $SO(2)$ leads to trigonometric functions and, hence, Fourier analysis, as the simplest case of harmonic analysis on semi-simple Lie groups (Warner, 1972).

A Lie group acts on its Lie algebra $\mathfrak{g}$ by the adjoint representation and on the dual space $\mathfrak{g}^*$ by the coadjoint representation. The coadjoint orbits are symplectic submanifolds with respect to the natural Lie–Poisson structure on $\mathfrak{g}^*$, and are of importance in classifying representations (Kirillov, 1999), geometric mechanics, and geometric quantization (Woodhouse, 1992). The Euler equations of rigid body motion and of fluid mechanics are realized as the Lie–Poisson equations on, respectively, the Lie algebra of the Euclidean group and the infinite-dimensional diffeomorphism group (Marsden, 1992).

A transformation group is called a symmetry group of a system of differential equations if it maps solutions to solutions. Symmetry groups are effectively computed by solving the infinitesimal symmetry conditions, which form an overdetermined linear system of partial differential equations, usually amenable to automatic solution by computer algebra packages (Olver, 1993, 1995). Applications include integration of ordinary differential equations, determination of explicit group-invariant (similarity) solutions of partial differential equations, Noether's theorems relating symmetries of variational problems and conservation laws (Noether, 1918), bifurcation theory (Golubitsky & Schaeffer, 1985), asymptotics and blow-up (Barenblatt, 1979), and the design of geometric numerical integration schemes (Hairer et al., 2002).

Classification of differential equations and variational problems admitting a given symmetry group relies on its differential invariants. The simplest examples

are the curvature and torsion of space curves, and the mean and Gaussian curvatures of surfaces under the Euclidean group acting on $\mathbb{R}^3$. Cartan's method of moving frames, and its more recent extensions to general Lie group and Lie pseudo-group actions (Olver, 2001), provides a general mechanism for construction and classification of differential invariants, with applications to differential geometry, the calculus of variations, soliton theory, computer vision, classical invariant theory, and numerical methods.

Modern developments in applications of Lie group methods have proceeded in a variety of directions. General theories of infinite-dimensional Lie groups and algebras (Kac, 1990) and Lie pseudo-groups, arising in relativity, field theory, fluid mechanics, solitons, and geometry, remain elusive. Higher order or generalized symmetries, in which the infinitesimal generators also depend upon derivative coordinates, first proposed by Noether (1918), have been used to classify integrable (soliton) systems. Recursion operators are used to generate such higher order symmetries and, via Noether's theorem, higher order conservation laws (Olver, 1993). Most recursion operators are derived from a pair of compatible Hamiltonian structures, and demonstrate the integrability of bi-Hamiltonian systems. The higher-order symmetries also appear in series expansions of Bäcklund transformations in the spectral parameter.

LIFETIME

As the word implies, *lifetime* is a measure of the time that something manages to persist and properly function. Often lifetime is a statistically defined quantity, as is evident from thinking about the failure of light bulbs. Clearly, one can exactly measure the lifetime of any particular bulb at the cost of burning it out, but it is more interesting to know the probability of failure in a given interval of time for a particular type of bulb. To obtain this information, it is necessary to measure the average burnout rate for a large number of bulbs that have been manufactured under identical conditions and use that information to characterize bulbs newly manufactured under the same conditions. A related approach is used by actuaries, who compute risks and premiums for human life insurance.

Failure of a Nuclear Power Plant

Statistical ideas are sometimes applied to more special situations, for example, a nuclear power plant, where neighbors ask: “What are the chances of it blowing up or melting down?” Engineers usually answer with soothing words. “It’s very safe. This reactor can’t blow up, and it has less than a fifty percent chance of melting down in the next thousand years.” But the engineers have only built a few dozen plants, all of which seem to be working fine. How do they come up with such an estimate?

One procedure is to consider the various failure mechanisms (onset of corrosion, earthquakes, operators falling asleep, terrorist attacks, and so on), and assign a mean lifetime to each failure mechanism. Then the total failure probability up to time t_1 is defined as

$$P(t_1) = \int_0^{t_1} \frac{dt}{\tau}, \quad (1)$$

where τ is the mean lifetime, taking all failure mechanisms into account. If these mechanisms are independent (do not influence one another), then

$$\frac{1}{\tau} = \frac{1}{\tau_1} + \frac{1}{\tau_2} + \cdots + \frac{1}{\tau_N}, \quad (2)$$

where $\tau_1, \tau_2, \dots, \tau_N$ are mean lifetimes estimated for N failure mechanisms. (Note that the τ_i may be functions of time.) A key result of this simple formulation is that the total lifetime is less than the smallest constituent lifetime, making it imperative to consider all possible failure mechanisms.

Lifetime of a Quantum State

Given a quantum state $\psi(\mathbf{r})$, where $\mathbf{r}$ is a spatial coordinate, it is interesting to know the mean time (τ) before ψ makes a transition (decays) into one of N other states: $\phi_1(\mathbf{r}), \phi_2(\mathbf{r}), \dots, \phi_N(\mathbf{r})$. According to “Fermi’s Golden Rule”, the transition probability into ϕ_i is proportional to the square of an overlap integral (Slater, 1951; Dirac, 1935)

$$|\langle \psi | \phi_i \rangle|^2 \equiv \left[\int \psi \phi_i^* d\mathbf{r} \right]^2; \quad (3)$$

thus the total lifetime is

$$\tau \propto \frac{1}{|\langle \psi | \phi_1 \rangle|^2 + |\langle \psi | \phi_2 \rangle|^2 + \cdots + |\langle \psi | \phi_N \rangle|^2}. \quad (4)$$

Although this equation is simple to write, it is difficult to compute because computation requires detailed knowledge of the wave functions of all states into which ψ can decay. Just as with a nuclear power plant, the total lifetime will be less than the smallest individual decay time, but τ is easier to measure, as it is often a small fraction of a second.

Soliton Lifetimes

When John Scott Russell first observed a hydrodynamic soliton on the “happiest day of [his] life” in August of 1834, he was struck by its remarkable stability, giving him time to follow it on horseback until it became “lost in the windings of the canal” (Russell, 1844). Although this and subsequent observations suggest that solitons are long-lived objects, the conclusion is somewhat misleading. It is the spatial localization of soliton energy that persists in time rather than the energy itself. Detailed perturbation calculations for the Korteweg-de Vries equation and for the nonlinear Schrödinger equation show that the times for energy decay under dissipative perturbations are less for nontopological solitons than for delocalized wave packets (Scott, 2003). Solitons of the sine-Gordon (SG) equation, on the other hand, have infinite lifetimes, as their decay is prevented by a topological constraint. Thus, the kinetic energy of a SG kink decays (the soliton

slows to a stop), but its rest mass does not disappear. The property of topological stability is shared by Skyrmions, which makes these objects interesting as models for elementary particles.

In studies of nontopological solitons in molecular crystals and of biological solitons, lifetime is a central issue, as the energy must remain localized long enough to be of technical or biological interest. When such solitons are also quantum objects (as is often the case), accurate lifetime calculations require estimates of the type sketched in Equation (4). This is a daunting theoretical task for three reasons: the wave function of a quantum soliton (ψ) is quite complicated (Davydov, 1991; Scott, 2003), biological molecules are often irregular structures for which all the possible final states $\{\phi_i\}$ are not known, and the temperatures at which biological organisms exist (ca. 300 K) introduce structural uncertainties that depend irregularly on time.

Using femtosecond pump-probe spectroscopy, however, it has recently become feasible to measure lifetimes in molecular crystals of the order of a picosecond or more (Elsaesser et al., 2000). Importantly, the response of such observations is null unless nonlinear effects are present, which occurs only for localized energy; thus the measurements focus specifically on soliton-like entities. From data produced by such experiments, the relevance of various theoretical proposals for solitons in molecular crystals and biomolecules should become better understood in coming years.

LINEARIZATION

Linear systems are much easier to analyze than nonlinear systems because they satisfy the superposition principle, which can be stated as follows: if R_1 is the output of a linear system to input S_1 and R_2 is the output to input S_2 , then the output to the cumulative input $aS_1 + bS_2$ is $aR_1 + bR_2$. Applied iteratively, this property allows the inputs and outputs of a linear system to be decomposed in various ways to simplify analysis. From a more general perspective, linear systems do not confuse the lines of causality between the input and output (stimulation and response) of a linear system. Fully nonlinear systems, on the other hand, do not share this useful property; thus, the causal implications of each stimulation must be individually studied.

Linearization is an attempt to carry some of the attractive properties of linear systems into the nonlinear domain. Linearization methods can be classified in two approaches: reductions of nonlinear systems to linearized approximations for small perturbations and extensions of linearized approximations to weakly nonlinear systems. Linearization methods of the first approach are used for stability analyses of special solutions of a nonlinear system, such as critical points, periodic orbits, solitary waves and periodic waves. In the neighborhood of such special solutions of nonlinear systems, linear equations are derived for small perturbations that are then studied using standard methods (Fourier or Laplace transforms, Green functions, etc.). Linearization methods of the second approach are based on specific parameters of a linearized system, such as dominant eigenvalues or resonant wave numbers. Thus, linearized systems are extended to weakly nonlinear systems, such as normal forms and amplitude equations, by means of asymptotic multiple scale expansion methods and Fredholm's alternative theorem for linear nonhomogeneous equations.

For systems of partial differential equations (PDEs), linearization methods can be illustrated with the example of a nonlinear Schrödinger (NLS) equation (Whitham, 1974):

$$iu_t + u_{xx} - (\omega_0 + \omega_2|u|^2)u = 0, \quad (1)$$

where ω_0 and ω_2 are parameters such that $\omega_2 > 0$ and $\omega_2 < 0$ occur for defocusing and focusing cases, respectively. The NLS equation (1) has a constant wave solution of the form:

$$u_0(x, t) = a e^{-i(\omega_0 + \omega_2 a^2)t}, \quad (2)$$

where the wave frequency $\omega = \omega_0 + \omega_2 a^2$ depends on the constant wave amplitude a . Linearizing the NLS equation (1) at the wave solution (2), one expands $u(x, t)$ as

$$u(x, t) = a e^{-i(\omega_0 + \omega_2 a^2)t} [1 + V(x, t) + iW(x, t)], \quad (3)$$

where V and W are real. When the expansion is substituted into the NLS equation and the nonlinear terms in V and W are neglected, the linearized problem can be transformed to the linear Boussinesq equation (4) with constant coefficients:

$$W_{tt} - 2\omega_2 a^2 W_{xx} + W_{xxx} = 0. \quad (4)$$

The Fourier spectrum of the linear Boussinesq equation consists of two counter-propagating waves:

$$W(x, t) = W_+ e^{ikx - i\Omega(k)t} + W_- e^{ikx + i\Omega(k)t}, \quad (5)$$

where $\Omega(k) = k\sqrt{2\omega_2 a^2 + k^2}$. When $\omega_2 > 0$ (the defocusing case), the wave spectrum is stable, that is, $\Omega(k)$ is real for any k . When $\omega_2 < 0$ (the focusing case), the wave spectrum is unstable, that is, $\Omega(k)$ is complex for an interval of k , namely for $0 < k < \sqrt{2|\omega_2|}a$. Thus, the linearization method of the first approach enables us to check stability of the constant wave solutions of the NLS equation.

The linear Boussinesq equation (4) with $\omega_2 > 0$ is a hyperbolic system. With dispersive effects neglected in a long-wave approximation, the Boussinesq equation reduces to the wave equation: $W_{tt} - c^2 W_{xx} = 0$, where $c^2 = 2\omega_2 a^2$. The wave equation has a solution in the form of two dispersionless counter-propagating waves: $W(x, t) = W_+(x - ct) + W_-(x + ct)$. Unidirectional long-wave, small-amplitude approximation can be captured by the asymptotic multi-scale expansion method in the perturbation series (Zakharov & Kuznetsov, 1986):

$$u(x, t) = a e^{-i(\omega_0 + \omega_2 a^2)t} \times \left[1 + i\varepsilon R(\xi, \tau) + \varepsilon^2 \left(\frac{1}{c} R_\xi - R^2 \right) + O(\varepsilon^3) \right], \quad (6)$$

where $\xi = \varepsilon(x - ct)$, $\tau = \varepsilon^3 t$, and ε is a small parameter. Applying the Fredholm's alternative theorem to a linear nonhomogeneous equation at order $O(\varepsilon^3)$, one can derive the Korteweg-de Vries (KdV) equation for $W = R_\xi$:

$$-2cW_\tau - 6cWW_\xi + W_{\xi\xi\xi} = 0. \quad (7)$$

With quadratic nonlinear terms neglected, the KdV equation (7) reproduces the dispersion relation of the linear Boussinesq equation, which has been reduced in the unidirectional long-wave approximation. Thus, the linearized method of the second approach enables us to derive the nonlinear evolution equation for wave propagation over the background of the constant wave solution of the NLS equation (1).

Linearization methods for systems of ordinary differential equations (ODEs) are illustrated with the example of an autonomous nonlinear dynamical system (Glendinning, 1994):

$$\frac{du}{dt} = f(u), \quad (8)$$

where $\mathbf{u} = \mathbf{u}(t)$ is a vector observable and $\mathbf{f}(\mathbf{u})$ is a vector nonlinear function. Critical points of the dynamical system occur for $\mathbf{u} = \mathbf{u}_0$ such that $\mathbf{f}(\mathbf{u}_0) = 0$. Linearizing the nonlinear system (8) at the critical point $\mathbf{u}_0$, one expands $\mathbf{u}(t)$ as

$$\mathbf{u}(t) = \mathbf{u}_0 + \mathbf{v}(t). \quad (9)$$

Neglecting quadratic terms in $\mathbf{v}(t)$ reduces the linearized problem to the linear system with constant coefficients:

$$\frac{d\mathbf{v}}{dt} = \mathcal{J}\mathbf{v}, \quad \mathcal{J} = \nabla_{\mathbf{u}}\mathbf{f} \Big|_{\mathbf{u}=\mathbf{u}_0}, \quad (10)$$

where $\mathcal{J}$ is the Jacobian matrix. Solutions of the linearized system (10) depend on eigenvalues and eigenvectors of the Jacobian matrix: $\mathcal{J}\mathbf{w} = \lambda\mathbf{w}$. If all eigenvalues are located in the left half-plane of λ , that is, $\text{Re}(\lambda) < 0$, then the critical point $\mathbf{u}_0$ is asymptotically stable and the perturbation $\mathbf{v}(t)$ decays to zero exponentially in t . If there exists at least one eigenvalue in the right half-plane of λ , then the critical point $\mathbf{u}_0$ is linearly unstable and the perturbation $\mathbf{v}(t)$ grows exponentially in t .

Some or all eigenvalues may be located at the imaginary axis of λ , that is, $\text{Re}(\lambda) = 0$. In such systems, when no other eigenvalues exist for $\text{Re}(\lambda) > 0$, the critical point $\mathbf{u}_0$ is neutrally (weakly) stable. Perturbations may however grow algebraically in t , if eigenvalues of λ are multiple with algebraic multiplicity exceeding the geometric multiplicity. Local linearization is often insufficient for full description of such weak instability and the nonlinear stability analysis is desired.

When eigenvalues cross or coalesce on the axis $\text{Re}(\lambda) = 0$, bifurcations may occur in the spectrum of a linearized system (Glendinning, 1994). Normal forms for bifurcations can be derived by extending the linearized system into the nonlinear domain. For example, a Hopf bifurcation occurs when two simple eigenvalues $\lambda = \Gamma(\varepsilon) + i\Omega(\varepsilon)$ and $\bar{\lambda} = \Gamma(\varepsilon) - i\Omega(\varepsilon)$ cross the imaginary axis at the bifurcation parameter $\varepsilon = 0$, such that $\Gamma(0) = 0$ and $\Omega(0) = \Omega_0$. The normal form for the Hopf bifurcation can be derived by the asymptotic multi-scale expansion method in the perturbation series:

$$\mathbf{u}(t) = \mathbf{u}_0 + \varepsilon [A(T)\mathbf{w}e^{i\Omega_0 t} + \bar{A}(T)\bar{\mathbf{w}}e^{-i\Omega_0 t}] + O(\varepsilon^2), \quad (11)$$

where $T = \varepsilon^2 t$ and $\mathbf{w}$ is the eigenvector of $\mathcal{J}\mathbf{w} = \lambda\mathbf{w}$ for $\lambda = i\Omega_0$ at $\varepsilon = 0$. The normal form for Hopf bifurcation follows from the Fredholm's alternative theorem at order $O(\varepsilon^3)$ in the form

$$\frac{dA}{dT} = [\Gamma'(0) + i\Omega'(0)]A - \beta(0)|A|^2 A, \quad (12)$$

where $\beta(0)$ is constant. $A(T)$ bifurcates into a periodic orbit at the Hopf bifurcation when $\Gamma'(0)\text{Re}(\beta(0)) > 0$.

Thus, linearization methods allow for linear and nonlinear stability analyses, resulting in simplifications of the nonlinear dynamical system (8).

LIQUID CRYSTALS

Discovery and Basic Properties

Liquid crystals do not follow the conventional classification of matter into three states: gas, liquid, and solid. In solids the orientation and position of the molecular building blocks are well determined, whereas in liquids the molecules move around in a disordered mixture. In liquid crystals the molecules can change their position, but their orientation is largely determined by neighboring molecules. The liquid crystal phase was discovered by Friedrich Reinitzer in 1888, when he noticed that solid cholesterol benzoate melted at 145°C into a scattering liquid crystal phase which transformed into a clear liquid after further heating to 178°C (Priestly et al., 1976, Chapter 2).

The type of ordering is related to the shape of the molecules or mesogens building the liquid crystal (De Gennes & Prost, 1993, Chapter 1). Calamitic molecules are rod-shaped and form nematic (molecules are aligned) or smectic phases (molecules are aligned and ordered in layers) as shown in Figure 1. Discotic molecules are disc-shaped and form nematic or stacked phases (with the molecules stacked on top of each other). The ordering of the molecules is not perfect due to thermal motion. With increasing temperature, ordering decreases until the liquid crystal is transformed into an isotropic liquid. Because the phase transitions are

Figure 1. Different phases of liquid crystal materials. (a) isotropic, (b) nematic, (c) smectic-A, (d) smectic-C, (e) cholesteric.

related to temperature, these materials are called thermotropic liquid crystals. The organic molecules have low molecular weight (200–500) and can go through several phases from low to high temperature: solid–smectic-C–smectic-A–nematic–liquid (Figure 1). Chiral (handed) molecules do not have mirror symmetry and this may lead to a cholesteric phase in which the nematic orientation rotates slowly from one layer to the next (Figure 1e). Chiral phases have the property to reflect circularly polarized light that has the same handedness and periodicity as the molecule's structure. In lyotropic liquid crystals which have one hydrophobic and one hydrophilic part, the crystalline ordering depends on the concentration of certain molecules in the solvent. At very low concentrations individual molecules move freely in the liquid, at higher concentrations droplets, cylinders, or planes of attached molecules can be formed. Lyotropic liquid crystals are important in biological systems, in cell membranes, and dispersions (De Gennes & Prost, 1993, Chapter 1).

The nematic and smectic-A phases have uniaxial symmetry with the preferential axis parallel with the molecules. The preferential axis is characterized by a vector, the director $\hat{n}$. Other properties such as permittivity, refractive index, magnetic susceptibility, and conductivity are described by a tensor. The index of refraction of calamitic liquid crystals may, for example, vary between $n_{\perp}=1.5$ and $n_{\parallel}=1.6$. The smectic-C phase has biaxial properties. The deformation of a liquid crystal leads to elastic energy. The energy in nematic liquid crystals is due to three types of variations in the orientation: splay, twist, and bend (see De Gennes & Prost, 1993, Chapter 3; Blinov & Chigrinov, 1994, Chapter 4). The elastic energy is then expressed by the following equation:

$$F_{\text{elastic}} = \frac{1}{2} (K_{11} (\nabla \cdot \hat{n})^2 + K_{22} (\hat{n} \cdot \nabla \times \hat{n})^2 + K_{33} (\hat{n} \times \nabla \times \hat{n})^2). \quad (1)$$

Surfaces can prefer either homeotropic (perpendicular) or parallel alignment of the director. If the interface is treated by rubbing a polyimide surface layer, this dictates a preferential azimuth for the director. The minimization of the combined elastic energy and surface energy determines the orientation of the director between the surfaces. This can lead to a pure twist as shown in Figure 2.

Figure 2. Nematic liquid crystal between two glass plates. The grid represents the alignment layer and the arrow the rubbing direction. Left: antiparallel rubbing with all molecules parallel; Middle: 90° twisted nematic; Right: when a voltage is applied between the electrodes, the molecules tilt.

Nonlinear Properties

In smectic liquid crystals, linear elasticity theory and linear hydrodynamics no longer hold because higher order terms come into play in the elastic energy (De Gennes & Prost, 1993, Chapter 8). The elasticity constants then depend on the deformation strength and this can lead to undulation instabilities, buckling, or focal conic structures. In a similar way, hydrodynamic nonlinearities yield frequency-dependent viscosities. If liquid crystal is illuminated with a high optical power, the physical properties may be modified. The processes leading to optical nonlinearities can be of electronic or non-electronic origin (Khoo, 1995). Electronic nonlinear effects involve processes in which the electronic wave functions of the liquid crystal molecules are perturbed by the optical field. These very fast processes are similar to electronic nonlinearities in solid crystals. These processes lead to second and third harmonic generation and optical phase conjugation (Khoo, 1995). Beside the electronic structure of the molecules, other physical properties can change because of an applied optical field, such as the molecular structure or orientation, the temperature, and the density (Elston & Samuels, 1998, Chapter 6). Slow temperature effects occur when a liquid crystal in a nematic phase is heated by an optical beam. The difference between the ordinary and extraordinary index of refraction decreases until the liquid crystal reaches the transition temperature and becomes isotropic. Another important effect is the molecular reorientation by the optical field. In the static case, the molecules will reorient due to the difference in dielectric constant ($\epsilon_{\parallel}$ and $\epsilon_{\perp}$); and in the optical case, due to the difference in refractive index ($n_{\parallel}$ and $n_{\perp}$).

Applications

Because of the anisotropy in the permittivity (or magnetic susceptibility), calamitic molecules with $\epsilon_{\parallel} > \epsilon_{\perp}$ prefer to orient their long axis parallel with an applied electric (or magnetic) field. By applying a voltage over a cell filled with liquid crystal, it is possible to make the molecules tilt out of the plane, as illustrated in Figure 2. In a uniaxial liquid crystal,

linearly polarized ordinary and extra-ordinary waves propagate with refractive indices $n_{\perp}$ and n_e (with n_e between $n_{\parallel}$ and $n_{\perp}$) (Iizuka, 2002, Ch.4). Because of the difference in propagation speed, the polarization state of the combined wave changes continuously. In a twisted nematic display (Figure 2), the linearly polarized light roughly follows the orientation of the director (Mauguin regime) and rotates over 90° (Priestly et al., 1976, Chapter 14). If the top polarizer is also rotated over 90° compared to the bottom polarizer, all light will be transmitted. If a voltage is applied to the cell and the molecules orient perpendicularly, the linear polarization is unchanged, and no light passes through the analyser. Cholesteric liquid crystals appear in nature, for example, in the cuticle of insects. The result is a colored and polarized reflection, depending on the angle of observation.

LOCAL MODES IN MOLECULAR CRYSTALS

Energy transfer in molecular crystals occurs through exciton hopping from molecule to molecule. It is possible, however, that nonlinear localization takes place due to coupling between excitonic and vibrational degrees of freedom, transforming the exciton into a local mode. Such a mode is generated by an effective local nonlinear potential induced by the exciton-phonon coupling, and it has features similar to a polaron, a soliton, and a breather.

The experimental search for nonlinear local modes was initiated by Careri in the early 1970s in crystalline acetanilide ($\text{CH}_3\text{CONHC}_6\text{H}_5$), or ACN, which has structure similar to a polypeptide; thus, positive findings in ACN could be of biological significance. In particular, if nonlinear local modes exist and are sufficiently long-lived, they could be agents of energy transfer in biomolecules.

In ACN and in proteins, one finds hydrogen-bonded quasi-one-dimensional polypeptide chains with the following structure:

Careri focused on the amide-I ($\text{C}=\text{O}$ stretching) vibration and found its infrared absorption spectrum to have two peaks: a "normal" one at 1665 cm^{-1} and an "anomalous" one at 1650 cm^{-1} . The basic feature of the latter is its strong temperature dependence and its disappearance at biological temperatures, as shown in Figure 1.

In 1982, Careri and Scott hypothesized that this anomalous peak is a spectral signature of a self-trapped state similar to the Davydov soliton, while the normal peak is the delocalized free exciton of the amide-I vibration. An approximate way to represent the ACN local mode is by assuming an adiabatic separation between the faster amide-I exciton vibration and a slower local (Einstein) oscillator with which the hydrogen bond interacts. The corresponding Hamiltonian has three terms:

$$H = H_{\text{ex}} + H_{\text{ph}} + H_{\text{int}}, \quad (2)$$

where

$$\begin{aligned} H_{\text{ex}} &= \sum_n \left[\varepsilon_0 a_n^\dagger a_n - J (a_n^\dagger a_{n+1} + a_n^\dagger a_{n-1}) \right], \\ H_{\text{ph}} &= \frac{1}{2} \sum_n \left[\frac{p_n^2}{m} + m \omega_0^2 q_n^2 \right], \\ H_{\text{int}} &= \chi \sum_n q_n a_n^\dagger a_n. \end{aligned} \quad (3)$$

Figure 1. Infrared absorption spectra of crystalline acetanilide in the region of the amide-I mode. The free exciton peak is at 1665 cm^{-1} while the anomalous peak that is at 1650 cm^{-1} has strong temperature dependence and is associated with a self-trapped state (Careri et al., 1984).

Here $a_n^\dagger$ (a_n) creates (destroys) a quantum of amide-I excitation of energy ε_0 at the n th CO unit, J is the energy of exciton-exciton interaction between adjacent CO units, p_n and q_n are the momentum and position, respectively, of the local Einstein oscillator at the n th location representing a low frequency optical mode, and χ determines the strength of the interaction between the exciton and Einstein mode.

One way to analyze this complex problem is by treating the slow ($p_n \approx 0$) Einstein oscillators classically while evaluating the expectation value of the total Hamiltonian with respect to the exciton wave function $|\Psi\rangle = \sum_n c_n(t) a_n^\dagger |0\rangle_{\text{ex}}$, where $|0\rangle_{\text{ex}}$ is the exciton system vacuum. Variational minimization of $\mathcal{H} \equiv \langle \Psi | H | \Psi \rangle$ with respect to the oscillator variable q_n leads to $q_n = -\chi / (m\omega_0^2) |c_n(t)|^2$, which upon substitution to $\mathcal{H}$ transforms the latter to the classical Hamiltonian

$$\mathcal{H} = \sum_n \left[\varepsilon_0 |c_n|^2 - J (c_n^* c_{n+1} + c_n^* c_{n-1}) - \frac{\chi^2}{2m\omega_0^2} |c_n|^4 \right]. \quad (4)$$

Hamilton's equations then lead to a discrete self-trapping system or a discrete nonlinear Schrödinger (DNLS) equation:

$$i\hbar \dot{c}_n + J(c_{n+1} + c_{n-1}) + \frac{\chi^2}{m\omega_0^2} |c_n|^2 c_n = 0. \quad (5)$$

This equation admits two types of solutions: one is an extended plane wave corresponding to the free exciton, while the other is localized and corresponds to a self-trapped state. The difference of the energies of these two solutions is

$$E_b = \frac{\chi^2}{2m\omega_0^2} - 2J, \quad (6)$$

corresponding to the binding energy of the self-trapped state. A combination of calculations and fitting to data suggests that $J \approx 4 \text{ cm}^{-1}$, $\chi^2 / m\omega_0^2 \approx 45 \text{ cm}^{-1}$, and E_b is equal to $1665 - 1650 = 15 \text{ cm}^{-1}$.

This picture is in accord with the presence of the two peaks in the amide-I region shown in Figure 1. Use of these parameter values in the context of a more sophisticated model gives also the correct temperature dependence of the anomalous peak. Because in the present case $J \ll \chi^2 / m\omega_0^2$, the local mode can also be viewed as a DNLS discrete breather close to the anti-continuous limit (where $J \rightarrow 0$).

Although the above proposed was furnished in the 1980s, both the essence of Davydov's idea as well as its specific application to ACN were challenged during this period. The possibility that the anomalous peak is a result of Fermi resonance of the amide-I mode with an overtone of an alternative ACN vibrational mode

was suggested as well as a possible structural source for the mode. These possibilities were to a large degree eliminated by the experimental work of Barthes and her collaborators. Definitive experimental information on the ACN local mode was furnished in 2002 by Edler and Hamm.

Using time-resolved pump-probe experiments with infrared beams of femtosecond duration, Edler and Hamm were able to excite the amide-I region and follow the time development of the various modes in that region. Their experiments showed a clear difference in the behavior of the normal and anomalous modes with the latter one being strongly anharmonic. Although the lifetime of the anomalous mode was only about 2 ps, return of this energy to the ground state took about 35 ps. Thus, the local mode initially relaxes into a state that is either spectroscopically dark or outside the spectral window of the probe. Interestingly, similar pump-probe experiments for the region of the NH stretching demonstrate the presence of nonlinear local mode structure in this range as well.

The initial experiments of Careri, the subsequent work of Barthes, and finally the experiments of Edler and Hamm along with Davydov's theory and its application to ACN by Scott present a convincing 30-year story that attributes the source of the anomalous ACN peak to a highly localized, relatively short-lived self-trapped state.

Another molecular crystal with different structure that is believed to form nonlinear local modes is the halide-bridged mixed-valence transition metal complex $\{[\text{Pt}(\text{en})_2][\text{Pt}(\text{en})_2\text{Cl}_2](\text{ClO}_4)_4\}$, where en = ethylenediamine. In PtCl, essentially one-dimensional chains of platinum alternating with chlorine atoms are formed, and an intra-molecular vibrational excitation of the PtCl₂ trimer caused by energy transfer between Pt⁴⁺ and Pt²⁺ seems to become effectively localized as a result of coupling with other crystal vibrational modes. Raman spectra show a clear red-shifted PtCl overtone spectrum induced by anharmonicity that reduces in PtBr crystals due to smaller effective anharmonicity and disappears in PtI due to absence of nonlinearity. A multiquanta generalization of the theoretical ACN approach of Equations (1)–(4) demonstrates that the overtone redshifts in the PtCl Raman spectrum can be accounted for quantitatively as well as qualitatively by a nonlinear local mode picture.

LOCAL MODES IN MOLECULES

The local mode model was introduced in the 1970s to describe highly excited vibrational overtone states. It has been used to describe XH stretching overtone spectra where X is some heavier atom like C, N, or O. However, the genesis of the local mode model in molecules dates back to the work of J.W. Ellis (1929). Ellis measured the overtone spectrum of benzene in the liquid phase to $\Delta\nu_{\text{CH}} = 8$ (a transition from the ground vibrational state to a state with 8 quanta in CH-stretching). He found that the spectra were pseudo-diatomic in character, in that the CH overtone frequencies could be fitted by a simple Birge–Sponer relationship that had been used to describe a diatomic anharmonic oscillator. Thus, if the observed overtone peak frequencies, $\tilde{\nu}_{v_0}$, are divided by v , the number of CH-stretching quanta in the excited overtone state, and plotted versus v , a straight line is obtained. The slope yields the local mode anharmonicity, $\tilde{\omega}_x$, and the intercept can be used to determine the local mode frequency, $\tilde{\omega}$.

$$\tilde{\nu}_{v_0}/v = \tilde{\omega} - (v + 1)\tilde{\omega}_x. \quad (1)$$

In 1968, Henry and Siebrand used the localization ideas of Ellis to model the overtone spectrum of benzene on the basis of the assumption that the six local CH-stretching modes were anharmonic but only weakly coupled (Henry & Siebrand, 1968). They derived values for CH-stretching anharmonicity constants expressed in the normal mode basis and calculated the energies of all of the components of the overtone bands expressed in terms of normal modes. At $\Delta\nu_{\text{CH}} = 6$, there are 462 such components of which 150 (the 75 doubly degenerate E_{1u} states) are allowed. The spectra were then modeled on the basis of a weighted combination of the allowed normal modes. Subsequently, Hayward and Henry postulated that the radiation field selectively excites only the most anharmonic of the normal mode

components (Hayward & Henry, 1975). In such a state, all the vibrational energy is effectively localized in one XH bond (X = C, N, O, etc.) and absorption to this pure local mode state is said to account for the overtone spectra. Some of these ideas had been published in 1936 in Germany by Mecke and his collaborators (Mecke & Ziegler, 1936). However, Mecke's work seemed to have been largely unknown and ignored. The description that emerges is that XH-stretching overtone spectra can be described by a local mode model in which the local oscillators are anharmonic but only weakly coupled. The radiation field selectively excites a state whose components have all of the vibrational energy localized in one of a set of equivalent XH bonds. Such a description predicts only a single transition for a given type of XH oscillator in agreement with experiment. The local mode model is now generally accepted, and because of the localization of energy for spectrally active states in a single chemical bond, XH-stretching overtone spectra are very sensitive to bond properties. Such spectra have been used to investigate molecular structure, molecular conformation, intermolecular forces, nonbonded intramolecular interactions, and intramolecular vibrational energy redistribution.

The Harmonically Coupled Anharmonic Oscillator Model

In a molecule like water, the two OH bonds can be treated as Morse potentials. In accord with the local mode model, the OH oscillators are anharmonic but only weakly coupled. It turns out that this off-diagonal potential and kinetic energy coupling is well approximated by the rules that govern coupling of harmonic oscillators.

The harmonically coupled anharmonic oscillator (HCAO) model was formulated independently by Mortensen et al. (1981) and by Child & Lawton (1981). Coupling is allowed only between states within a given vibrational manifold, that is, between states with the same value of the XH-stretching vibrational quantum number v . Coupling is restricted to the harmonic limit where oscillator population differs by ± 1 . All of the parameters in this model are obtained either directly from the spectra or from ab initio calculations.

The model has been very successful in accounting for the observed energies of overtone peaks in XH-stretching overtone spectra and, thus, has proved useful in the assignment of these spectra. It has been generalized to more than two equivalent oscillators and to sets of non-equivalent oscillators. No identification of the wave functions is needed for the HCAO model to calculate peak energies. However, if one uses a basis set consisting of products of one-dimensional Morse oscillators, the HCAO model can be used to generate vibrational wave functions. If such wave functions are used along with ab initio calculations of dipole moment

functions (expanded in local coordinates), simple but highly successful calculations of overtone intensities are possible (Kjaergaard et al., 1990).

Overtone Intensities

Typically, these calculations: (i) identify transitions to pure local mode states, whose components have all of the vibrational energy localized in one of a set of equivalent XH oscillators, as the dominant peaks for $\Delta\nu_{XH} \geq 3$; (ii) indicate that the intensity of these pure local mode peaks is determined primarily by second-order diagonal terms involving $\partial^2\mu/\partial R^2$ in the dipole-moment operator μ ; (iii) account for the fall-off in intensity with increasing ν and the intensity distribution within a given manifold; (iv) account for the intensity distribution at $\Delta\nu_{XH}=2$ where coupling between the local oscillators is important; and (v) account for relative intensities for different oscillators within a molecule. For example, calculations on cyclohexane (Kjaergaard & Henry, 1992) and naphthalene (Kjaergaard & Henry, 1995) successfully predict the relative intensities of the two non-equivalent ring hydrogens. These calculations have also been applied to the determination of accurate absolute overtone intensities for a number of species that are important in atmospheric photochemistry so that effects on the absorption of solar radiation can be estimated (Fono et al., 1999; Vaida et al., 2001).

One surprising result in these intensity calculations is that electron correlation in the dipole moment function affects the calculated fundamental intensity but has no significant effect on overtone intensities. One factor in this insensitivity to correlation is likely to be the primary importance of nonlinear terms in the dipole moment operator.

The HCAO intensity model has been generalized to include torsional motion in the Hamiltonian and to include the torsional coordinate in the ab initio calculation of the dipole moment function. As a result of coupling between torsion and stretching, both in the Hamiltonian and through the dipole-moment function, a very large number of transitions carry intensity and contribute to the overall methyl spectral profile. This model has successfully accounted for the methyl spectral profiles in the overtone spectra of methyl substituted aromatic molecules (Kjaergaard et al., 2000).

One early interest in the local mode field was the possibility that these highly localized states could be pumped with high power lasers and the result would be selective bond photochemistry. To date, no practical example of such behavior has arisen. The reason probably lies in the very rapid decay of these highly vibrationally excited states on a subpicosecond timescale. The dynamics of these local mode states continues to be a very active research area.

LONG JOSEPHSON JUNCTIONS

The long Josephson junction is an excellent example of an experimental solid-state system that in a straightforward and measurable way, supports the existence and propagation of solitons (Parmentier, 1978; Pedersen, 1986; Ustinov, 1998). In this system, the soliton is called a fluxon, because it contains one quantum of magnetic flux, $\Phi_0 = h/2e \doteq 2.064 \times 10^{-15}$ webers (h is Planck's constant and e is the electron charge), in accord with the particle nature of solitons (Scott, 2003).

A Josephson junction consists of two weakly coupled superconductors separated by a thin (typically 1–10 nm) insulating layer. An important dynamical variable is the phase difference between the macroscopic quantum mechanical phases of the two superconductors, $\phi(x, t)$. Under an appropriate time normalization, the small Josephson junction obeys approximately the same equation as the damped and driven pendulum. If the Josephson junction is long with respect to an intrinsic length scale (called the Josephson penetration depth, of order 1–1000 μm), the equation becomes the damped and driven sine-Gordon equation (often called the perturbed sine-Gordon equation) (McLaughlin & Scott, 1978):

$$-\phi_{xx} + \phi_{tt} + \alpha\phi_t + \sin\phi = i. \quad (1)$$

Here, the damping parameter α (with typical experimental values in the range $0.01 < \alpha < 0.1$) is related to the Josephson junction parameters per unit area: conductance G , capacitance C , and supercurrent J ; thus $\alpha = G\sqrt{\hbar/2eCJ}$. Also $i = I_{\text{bias}}/I_0$ is a bias current normalized to the maximum Josephson current, x is the direction of the long side of the junction normalized to the Josephson penetration depth, and time t is normalized to the so-called plasma frequency, which corresponds to the pendulum oscillation frequency. The plasma frequency is of order 1–500 GHz, depending on fabrication parameters (composition and thickness of insulating layer, superconducting materials, etc.).

A particularly interesting solution to Equation (1) is the sine-Gordon soliton (kink), or rather a slightly modified kink because of the damping and bias terms. Such a kink carries one quantum of magnetic flux (an antikink carries a flux quantum pointed in the opposite direction), and it has a steady state velocity determined as a balance between energy input from the bias current (i) and losses stemming from α . This solution has particle-like properties, behaving approximately as a Lorentz invariant, relativistic particle with the velocity of light in the system being the limiting velocity. This so-called Swihart velocity is determined by the junction fabrication parameters and is typically 1–5% of the velocity of light in vacuum.

The simple form of the dynamical equation shown in Equation (1) refers to the so-called overlap geometry shown in Figure 1(a), in which the externally applied

Figure 1. Rectangular-shaped long Josephson junctions (not to scale). (a) Overlap geometry. (b) Inline geometry.

Figure 2. Other long junction geometries (bias not shown). (a) Eiffel junction. (b) Annular junction.

current is fed uniformly to the long dimension of the long Josephson junction. In addition to Equation (1), boundary constraints must be satisfied. For an overlap junction of length L , the longitudinal (x -directed) surface current (j) is zero at $x=0$ and $x=L$ if no external magnetic field is applied.

Because the long Josephson junction is typically fabricated using photolithographic and evaporation techniques borrowed from the semiconductor chip industry, it is easy to produce different geometries. Besides the overlap junction, inline junctions, Eiffel junctions, and annular junctions are of experimental and practical interest.

For the inline junction shown in Figure 1(b), the external current is fed from the narrow ends of the junction. The right-hand side of Equation (1) becomes zero, and the bias enters through the boundary conditions at $x=0$ and L . In the Eiffel junction shown in Figure 2(a), the width of the junction is varied in an exponentially tapered shape approximating that of the Eiffel tower. For reasons of energy conservation, the propagation becomes unidirectional, with the fluxon tending to move in the direction of decreasing junction width (Benabdallah et al., 1996, 2000). The Eiffel junction has been proposed as a dc to ac converter and a microwave oscillator.

The annular junction, shown in Figure 2(b), is like a long overlap junction where the two ends are

joined. For topological reasons connected with the superconducting phase quantization, periodic boundary conditions apply; that is, $j(0, t) = j(L, t) + 2p\pi$ with $p = 0, 1, 2, \dots$, where j is the longitudinal surface current. A relatively clean soliton (fluxon) can be studied here since there are no collisions with boundaries. The total number of fluxons minus antifluxons is a conserved number (p) and fluxons can only disappear in a fluxon-antifluxon annihilation processes, conserving the total flux in the ring. In a variant of the annular junction, periodic changes in the junction width give rise to deceleration and acceleration of the fluxons, thereby producing radiation (McLaughlin & Scott, 1978).

The long Josephson junction has a potential as a microwave oscillator in the hundreds of Gigahertz range (100–1000 GHz). This is a frequency range, interesting for applications such as fast superconducting electronics, radio astronomy, and satellite-to-satellite communication. In this frequency range, competing oscillators are often bulky, noisy, and expensive. Importantly, the line width of the fluxon oscillator with proper stabilization can become very narrow—of the order 50 kHz. Since the line width of a local oscillator sets the frequency resolution for a heterodyne receiver, this is an important property for spectroscopy and for determining the frequency of radio sources in the universe.

For radio astronomy (~ 100 –500 GHz), the standard today is a superconducting superheterodyne receiver, for which all components (mixer, local oscillator, filters, etc.) are fabricated in superconducting electronics, and the local oscillator is typically a long Josephson junction. In practice, two different schemes for a fluxon oscillator have been used. In one scheme, the fluxon propagates back and forth within the junction. At each collision with boundary some radiation is coupled out to an external circuit. The frequency of the radiation is given by the time of flight of the fluxon in the junction.

In another mode—the so-called flux flow mode—a unidirectional stream of fluxons is created. This can be done either by the above mentioned Eiffel junction or by applying a magnetic field that breaks the symmetry, giving rise to energy absorption at one end of the junction and energy creation at the other. With proper parameter adjustment, fluxons will be continuously created at one end of the junction, propagated through the junction, and absorbed in an external load (mixer) at the other end.

The power obtainable in such schemes is at best a few microwatts at 300–500 GHz with a narrow line width (of order 100 kHz). Nonetheless, this power level is sufficient for local oscillators of superconducting receivers.

As a concluding remark, we mention that it has been known since the early days of the long Josephson junction research, that the fluxon has properties related

to a relativistic particle. Recent experiments have demonstrated that it also has quantum mechanical properties (Wallraff et al., 2003).

LORENTZ GAS

The Lorentz gas is a model dynamical system generated by the motion of non-interacting point particles (“electrons”) in a field of immovable (infinitely heavy) spherical particles, called scatterers. The particles move by inertia according to Newton’s law and are reflected from the scatterers elastically. The scatterers may

overlap and are assumed to be randomly or periodically distributed.

Hendrik Lorentz introduced this model as a simplified version of the Drude model for metallic conduction of electricity (Lorentz, 1905). Lorentz's goal was to modify the Drude model in such a way that the Boltzmann equation becomes linear. This is so for the Lorentz gas because of the lack of interactions between particles, which do not influence the positions of the scatterers. As it is sufficient to consider just one moving particle, a one particle model is now usually called the Lorentz gas.

The Lorentz gas appeared to be an inadequate model to describe a gas of electrons in metals. However, it became one of the most popular models in non-equilibrium statistical mechanics, which is used to study the most fundamental problems such as irreversibility, the existence of transport coefficients, and the derivation of kinetic and hydrodynamic equations from mechanical laws. The Lorentz gas with random distribution of scatterers also serves as a relevant model of a dilute gas in equilibrium, consisting of a mixture of two types of (spherical) particles with one much larger and heavier than the other. Almost all collisions are between smaller and larger particles, rather than among smaller particles, even though there are many more smaller particles than heavy particles (Dettmann, 2000).

The kinetic stage of the Lorentz gas evolution is described by the Boltzmann equation, which refers to dilute gases. The appropriate limit procedure was suggested by Grad (1958) and is called the Boltzmann–Grad limit. In this limit, the density of a gas (density of scatterers) tends to zero while the mean free path of the moving particle remains constant. For the Lorentz gas, the kinetic Boltzmann equation goes in the Boltzmann–Grad limit into the linear Fokker–Planck–Kolmogorov equation for the corresponding Markov process. It has been proven for a dilute random Lorentz gas in the Boltzmann–Grad limit that the Boltzmann equation holds for almost any (Poisson distributed) configuration of scatterers (Boldrighini et al., 1983). This result allows a comparison of the theory with the results of computer experiments, because it refers to an individual configuration of scatterers rather than to characteristics averaged over the ensemble of all such configurations.

Rigorous results on the hydrodynamics of the Lorentz gas are available only for periodic configurations of scatterers. This problem for a random Lorentz gas currently looks hopeless because it can be reduced to a problem of random walks in random environments that is far beyond the present abilities of this theory. Clearly, the hydrodynamic equation for the Lorentz gas must be the diffusion equation because the momentum is not preserved in this model, and the conservation of energy is just equivalent to the conservation of

Figure 1. Periodic Lorentz gas: (a) With bounded free path. (b) With unbounded free path.

mass. Therefore, the diffusion coefficient is also the only transport coefficient in the Lorentz gas.

Consider a periodic Lorentz gas where a free path of the particle is uniformly bounded by some constant. The simplest such configuration of scatterers in the plane is obtained by taking the hexagonal lattice of sufficiently large scatterers (Figure 1(a)). Observe that a periodic Lorentz gas is just Sinai billiards (See **Billiards**) when restricted to an elementary cell of a periodic configuration of scatterers. Such a cell can always be chosen to be a rectangle $B = \{q = (q_1, q_2) : 0 \leq q_1 \leq b_1, 0 \leq q_2 \leq b_2\}$, where (q_1, q_2) are planar coordinates of the moving particle. Let the particle initially (at $t = 0$) have a random position in B and its velocity (which in a Lorentz gas can always be taken as equal to one) be also randomly distributed in the unit circle. Suppose that this distribution μ (in the direct product Π of B and the unit circle) has a well-behaved density with respect to the volume in Π . Then $x(t) = (q(t), v(t))$ is a random vector, where $q(t) = (q_1(t), q_2(t))$ is a position of the particle at time t and $v(t)$ is its velocity. Rescale trajectories of the particle by setting $q_t(s) = \frac{1}{\sqrt{t}} q(st)$, $0 \leq s \leq t$. The probability distribution μ on the initial conditions induces a probability distribution on μ_t on the set of all possible trajectories $q_t(s)$, $0 \leq s \leq t$. To study a hydrodynamic behavior one should consider large times. The measures μ_t converge (weakly) as $t \rightarrow \infty$ to a Wiener measure (Bunimovich & Sinai, 1981). This result provides a rigorous derivation of (time non-invertible macroscopic) hydrodynamic diffusion equations from first principles (time invertible microscopic Newtonian equations). It shows that at large scales in space and time, trajectories of the periodic Lorentz gas look the same as trajectories of the stochastic diffusion process. Indeed, the transition probabilities of Wiener processes are the fundamental solutions of the diffusion equation. The same result holds for the periodic Lorentz gas with bounded free path in dimensions ≥ 3 (Chernov, 1994).

According to the Einstein formula,

$$D = \frac{2}{d} \int_0^\infty \int_M [v(x(0)) \cdot v(x(t))] d\mu(x(0)) dt, \quad (1)$$

where d is a dimension, M is the phase space, and $v(x(0))$ is the velocity of the particle at the moment $t = 0$. The Einstein formula is the first in the infinite

hierarchy of Green–Kubo formulas that relate transport coefficients with the integrals of time correlations of some phase functions. Therefore, the problem of existence of the transport coefficients is reduced to an estimate of the rate of time-correlations decay, which for the periodic Lorentz gas is fast enough (Chernov & Young, 2000).

The condition that a free pass must be bounded is important. Periodic Lorentz gases with an unbounded free path (Figure 1(b)) behave super-diffusively rather than diffusively (Bleher, 1992) and time correlations there decay only according to a power law because the particle gets trapped for a long time in the part of the phase space with arbitrarily long free paths.

Until the 1960s, it was generally believed that time correlations in many-body systems decay exponentially. This opinion was based on the analysis of completing solvable models, such as Markov processes. Therefore, the discovery of long tails of time correlations in numerical experiments came as a surprise (Alder & Wainwright, 1967). It is now believed that time correlations in a random Lorentz gas decay according to a power law. This is confirmed by numerical experiments and physical theories but not by rigorous mathematical results.

Interesting models arise by placing the Lorentz gas in an external field. A periodic Lorentz gas in a magnetic field can demonstrate ergodic as well as integrable behavior (Berglund & Kunz, 1996). The Lorentz gas in a (weak) electric field becomes a non-Hamiltonian system, with the energy of the moving particle increasing indefinitely. One can connect this system to a thermostat to keep the energy fixed and to make the dynamics time reversible, whereupon it is possible to establish rigorously Ohm's law (Chernov et al., 1993). Presently, studies of the thermostated Lorentz gas are popular both in non-equilibrium statistical mechanics and in molecular dynamics (Dettmann, 2000).

LORENZ EQUATIONS

A revolutionary development in the realms of nonlinear science over the past four decades has been an understanding of how ubiquitously systems of deterministic equations exhibit complicated behavior. Although the possibility of complicated aperiodic solutions was known much earlier from the work of Henri Poincaré and George D. Birkhoff on the so-called three-body problem (the Earth, Sun, and Moon) in celestial mechanics in the late 19th and early 20th centuries, such behavior was believed to be exceptional (*See Poincaré theorems*).

Two crucial pieces of work in the 1960s, the first by Edward Lorenz in 1963 on a continuous model relating to weather prediction (*See Butterfly effect*) and the second by Stephen Smale in 1967 in the context of discrete mathematical maps, altered this perception completely, showing that complex aperiodic behavior is generic for most deterministic nonlinear systems.

The basic equations introduced by Lorenz are

$$\begin{aligned}\dot{x} &= \sigma(y - x), \\ \dot{y} &= rx - y - xz, \\ \dot{z} &= xy - bz,\end{aligned}\tag{1}$$

which were obtained by a drastic simplification of the fluid dynamical equations governing convection currents in the atmosphere. Equations (1) resulted from truncating a Fourier series description after the first few modes (Bergé et al., 1984), and the parameters σ

and r are physically important dimensionless numbers known, respectively, as the Prandtl and Rayleigh numbers in fluid mechanics.

Solutions of the Lorenz equations can be organized around a classification of their attractors (Glendinning, 1994; Strogatz, 1994; Nayfeh & Balachandran, 1995), which are regions of the space of physical variables or phase space (also called state space) to which solutions are attracted if the attractor is stable, or from whence they are repelled if the attractor is unstable.

Nonlinear systems may have several different kinds of attractors, including point attractors (also known as fixed, or critical, or equilibrium, points), isolated periodic attractors (or limit cycles), as well as more complex attractors called quasi-periodic and chaotic attractors. The nature and number of the attractors may change as the parameters (σ , r , and b) vary, leading to a qualitative change in behavior referred to as a bifurcation.

A straightforward calculation showed Lorenz that his system contracted volumes in phase space—a dissipative system. This meant that any ball or volume of initial conditions in the phase space must shrink down to zero volume at large times under evolutions governed by the Lorenz equations. In other words, any attractors of the system must have zero volume.

Also, the model has a critical point at the origin ($x = y = z = 0$) and a pair of critical points $C^\pm$ at $x = y = \pm \sqrt{b(r-1)}$ for $r > 1$. Lorenz's stability analysis showed that the first fixed point at the origin of the phase space is always stable for $r < 1$ and a global attractor to which all initial points (or initial conditions) in the phase space are attracted for this parameter range. For $r > 1$, he found that the first fixed point at the origin becomes linearly unstable and is longer a bona fide attractor. However, the new fixed points are stable for

$$1 < r < r_H = \frac{\sigma(\sigma + b + 3)}{\sigma - b - 1}. \tag{2}$$

In this parameter range, calculation shows that these fixed points coexist with an unstable limit cycle. At $r = r_H$, this limit cycle is absorbed by the fixed point in a bifurcation that is known as a subcritical Hopf bifurcation. The fixed points $C^\pm$ go unstable in the process, being transformed into saddle points.

For $r > r_H$, there are no simple stable point attractors, so Lorenz considered other stable limit cycles (periodic attractors) or solutions flying off to infinity. He showed that any possible limit cycles should be unstable for $r > r_H$ and also that all trajectories must eventually enter, and be confined within, a certain large ellipsoid.

Clearly, any attractor had to be relatively complex, and the trajectories could not cross while evolving on the attractor. Together with the earlier-mentioned fact of volume contraction (which means that any attractor to which the solution trajectories or orbits are attracted must have zero volume asymptotically in time), Lorenz

Figure 1. Lorenz attractor in (x, y, z) phase space for $\sigma = 10$, $r = 28$, $b = 8/3$.

was left with a perplexing question: What must such an attractor be like?

He numerically studied the case $\sigma = 10$, $r = 28$, $b = \frac{8}{3}$ with the $r > r_H = 24.74$ in Equation (2). He also chose initial conditions $(x, y, z) = (0, 1, 0)$ close to the saddle point nearer the origin. The resulting solutions in (x, y, z) phase-space, and for $x(t)$ as a function of time are shown in Figures 1 and 2, respectively, where the solution trajectory settles onto a strange butterfly-shaped attractor set after an initial transient. The clearly aperiodic dynamics on this attractor is emphasized in Figure 2. In addition, the attractor appears to be infinitesimally thin and thus satisfies the requirement of zero volume. Hence, all three requirements of aperiodicity of the dynamics on the attractor, zero volume, and nonself-crossing of the orbit were reconciled on this “strange attractor”—a term subsequently coined by Ruelle and Takens. Among other observations, Lorenz noted that this strange attractor has a self-similar structure at all scales, which is now a well-known feature of chaotic attractors.

Subsequent work has revealed that trajectories on chaotic attractors exhibit sensitivity to initial conditions (SIC) where initially contiguous phase points diverge exponentially in time. Other work, some still in progress (Abraham & Shaw, 1983; Bergé et al., 1984), has elucidated the complex process leading to the structure of strange attractors and the properties of the orbits on them. In particular, there is convergence of orbits along the stable manifolds of saddle fixed points (this enables dissipation or volume contraction to be satisfied), divergence of trajectories along the corresponding unstable manifolds (this accounts for SIC), and foldings leading to bounded strange attractors.

Based on a combination of topological and numerical ideas to reconstruct chaotic attractors from

Figure 2. A solution $x(t)$ for $\sigma = 10$, $r = 28$, $b = 8/3$.

Figure 3. A solution $x(t)$ for $\sigma = 1$, $b = 2$, $r = 1/9$.

time series such as that in Figure 2, numerical procedures have been developed to compute various properties such as the fractal dimension (a measure of the global dimension of the attractor in phase space), Lyapunov exponents (measures of sensitivity to initial conditions on the attractor), power spectra and autocorrelation functions, and the so-called Kolmogorov entropy (Nayfeh & Balachandran, 1995). In particular, the chaotic attractor in Figure 1 has a dimension of about 2.05; that is, it occupies a region of the phase space that has infinite area or fills up any area (since the dimension is greater than 2), but has zero volume (since the dimension is less than 3).

The occurrence of sensitivity to initial conditions as indicated by at least one positive Lyapunov exponent or the envelope of the autocorrelation function going to zero in finite time signify the eventual loss of memory of past history (or equivalently the impossibility of prediction far into the future), which are integral features of chaotic dynamics.

Note that the Lorenz equations also exhibit completely deterministic or nonchaotic behavior for isolated parameter sets obtained via Painlevé analysis that are the so-called integrable cases (Tabor & Weiss, 1981). Figure 3 shows the completely regular dynamics for the parameter set $\sigma = 1$, $b = 2$, $r = 1/9$. Note how much more regular and orderly, the behavior of $x(t)$ is than that shown in Figure 2.

In conclusion, two features of the Lorenz model continue to make it topical. First, it remains a useful

model in which to study essential basic features of chaotic systems. Second, the model has popped up in topical settings as diverse as atmospheric dynamos, lasers, and nonlinear optics, as well as the control of chaos (Ning & Haken, 1990; Pecora & Carroll, 1990; Nayfeh & Balachandran, 1995; Batchelor et al., 2000).

LYAPUNOV EXPONENTS

The sequence of powers A^k , $k = 1, 2, \dots$, of a complex number $A \neq 0$ has one of three types of asymptotic behavior: exponential growth, exponential decay, or constant, according to the modulus $|A|$. A similar situation holds for powers A^k , $k = 1, 2, \dots$, of an $n \times n$ matrix A . More precisely, for any vector $v \neq 0$, the following limit exists:

$$\lim_{k \rightarrow +\infty} \frac{1}{k} \log \|A^k v\| = \lambda(v). \quad (1)$$

The possible values of $\lambda(v)$, $\lambda_1 < \dots < \lambda_s$ are called Lyapunov exponents (LEs), and in this special case they are equal to $\log |a|$, where a is an eigenvalue of A (real or complex). Moreover, there is a strictly increasing sequence of subspaces in $\mathbb{R}^n$

$$\{0\} = V_0 \subset V_1 \subset \dots \subset V_s = \mathbb{R}^n, \tag{2}$$

such that $\lambda(v) = \lambda_i$ for all $v \in V_i \setminus V_{i-1}$, $i = 1, 2, \dots, s$. The difference of dimensions $m_i = \dim V_i - \dim V_{i-1}$ is called the multiplicity of the Lyapunov exponent λ_i . The rates of growth of k -dimensional volumes of k -dimensional parallelepipeds under the action of A are sums of appropriate Lyapunov exponents. For example, the exponential rate of growth of the n -dimensional volume is equal to $\log |\det A| = m_1 \lambda_1 + \dots + m_s \lambda_s$.

A similar situation occurs for products $A^k = A_k A_{k-1} \dots A_1$ when the sequence of matrices $A_1, A_2, \dots$ is periodic (by direct reduction to the constant case we obtain so-called Floquet multipliers, and the LEs are logarithms of their moduli).

In the general nonperiodic case, the key Oseledec Multiplicative Ergodic Theorem (OMET) states that the same scenario holds, when the matrices we multiply $(A_1, A_2, \dots)$ are supplied by a stationary stochastic process (with matrix values). In this case, the conclusions apply with probability one.

In the context of dynamical systems, the difference equation $x_{n+1} = \Phi(x_n)$, where $\Phi: M \rightarrow M$ is a diffeomorphism of a compact smooth manifold M (the phase space). For any ergodic invariant probability measure ν , the Lyapunov exponents are the limits

$$\lim_{k \rightarrow +\infty} ||D_x \Phi^k v|| = \lambda(v), \tag{3}$$

which exist for ν almost every $x \in M$ and all nonzero tangent vectors $v \in T_x M$. Thus, Lyapunov exponents characterize the growth in linear approximation of infinitesimal perturbations of initial conditions. Positive LEs lead to instability and negative LEs to stability for perturbations in the respective directions.

Applying OMET both to the future and the past (i.e., to Φ and to Φ^{-1}), we obtain a splitting of tangent spaces

$$T_x M = W_1 \oplus W_2 \oplus \dots \oplus W_s, \tag{4}$$

such that

$$\lim_{k \rightarrow \pm\infty} ||D_x \Phi^k v|| = \pm \lambda_i \tag{5}$$

for ν almost every $x \in M$ and all nonzero tangent vectors $v \in W_i(x)$. It is of direct interest to know if this infinitesimal behavior translates to the behavior of actual orbits of the nonlinear system. We introduce the stable $E^s(x)$ and unstable $E^u(x)$ subspaces, which are the direct sums of subspaces $W_i(x)$ with negative, respectively positive, LEs. It is the content of Pesin Theory that the subspaces E^s and E^u can be integrated almost everywhere, that is, for ν almost every

point $x \in M$ there are smooth submanifolds $W^s(x)$ and $W^u(x)$, which are at every point tangent to the stable and unstable subspaces, respectively.

The stable and unstable manifolds are crucial in understanding chaotic dynamics. Their importance stems from the fact that two orbits starting on one of these submanifolds have the same asymptotic behavior either in the future or in the past.

LEs are associated with the Kolmogorov–Sinai entropy. They enter into the Ruelle Inequality, which states that for any C^1 diffeomorphism Φ and any ergodic invariant probability measure ν

$$h_\nu(\Phi) \leq \sum_{\lambda_i > 0} m_i \lambda_i, \tag{6}$$

where $h_\nu(\Phi)$ is the K–S entropy. This inequality turns into equality (the Pesin formula) for absolutely continuous measures ν and C^2 diffeomorphisms. It was proven by Ledrappier and Young that equality holds if and only if ν is the Sinai–Ruelle–Bowen (SRB) measure.

For Hamiltonian systems (i.e., when Φ is a symplectomorphism), the LEs come in pairs of opposite numbers, which is related to the symmetry of spectra of symplectic matrices. Furthermore the subspace V_k is skew-orthogonal to V_{s-k} , $k = 1, 2, \dots, s$: a property shared with eigenspaces of symplectic matrices.

Although analytic formulas for LEs are almost non-existent, they can be readily obtained by numerical methods. Analytical estimates of LEs are available where all the matrices in question are J -separated for some quadratic form (field of forms) J . A matrix A is J -separated, if $J(Av) \geq 0$ for all v such that $J(v) \geq 0$.

MAGNETOHYDRODYNAMICS

Magnetohydrodynamics (MHD) is the special field of fluid dynamics that is concerned with the motions of electrically conducting fluids in the presence of magnetic fields. Flows of liquid metals or ionized gases (plasmas) are the main areas of applications of MHD.

For the theoretical description of MHD-problems, the basic equations of fluid dynamics must be supplemented by the Lorentz force $\mathbf{j} \times \mathbf{B}$ where $\mathbf{j}$ is the density of electric current and $\mathbf{B}$ is the magnetic flux density. To determine these fields Maxwell's equations are used in the magnetohydrodynamic approximation in which the displacement current is neglected. This represents a good approximation as long as the fluid velocity is small compared with the velocity of light. These equations together with Ohm's law for a moving conductor are given by

$$\begin{aligned}\nabla \cdot \mathbf{B} &= 0, \quad \frac{\partial}{\partial t} \mathbf{B} = -\nabla \times \mathbf{E}, \quad \nabla \times \mathbf{B} = \mu \mathbf{j}, \\ \mathbf{j} &= \sigma(\mathbf{v} \times \mathbf{B} + \mathbf{E}),\end{aligned}\quad (1)$$

where μ is the magnetic permeability of the fluid and σ is its electrical conductivity. These "pre-Maxwell" equations have the property that they are invariant with respect to a Galileo transformation, i.e., the equations remain unchanged in a new frame of reference moving with the constant velocity vector $\mathbf{V}$ relative to the original frame of reference. Indicating the variables of the new frame by a prime, we find

$$\begin{aligned}\mathbf{v}' &= \mathbf{v} - \mathbf{V}, \quad \frac{\partial}{\partial t'} = \frac{\partial}{\partial t} + \mathbf{V} \cdot \nabla, \\ \mathbf{B}' &= \mathbf{B}, \quad \mathbf{E}' = \mathbf{E} + \mathbf{V} \times \mathbf{B}, \quad \mathbf{j}' = \mathbf{j}.\end{aligned}\quad (2)$$

This invariance is the basis for the combination in MHD of Equations (1) with the equations of hydrodynamics in their usual nonrelativistic form. The application of MHD to plasmas is limited to sufficiently low frequency and long wavelength phenomena. If these conditions are not satisfied, two-fluid equations may be used.

Elimination of $\mathbf{E}$ and $\mathbf{j}$ from Equation (1) yields the equation of magnetic induction

$$\nabla \times \left(\frac{1}{\sigma \mu} \nabla \times \mathbf{B} \right) = \frac{\partial}{\partial t} \mathbf{B} + \nabla \times (\mathbf{v} \times \mathbf{B}), \quad (3)$$

which for a solenoidal velocity field $\mathbf{v}$ and a constant magnetic diffusivity $\lambda \equiv (\sigma \mu)^{-1}$ can be further simplified,

$$\left(\frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla \right) \mathbf{B} - \lambda \nabla^2 \mathbf{B} = \mathbf{B} \cdot \nabla \mathbf{v}. \quad (4)$$

This equation has the form of a heat equation with the magnetic field line stretching term on the right-hand side acting as a heat source. This interpretation is useful in the dynamo problem of the generation of magnetic fields by fluid motions (See **Dynamos, homogeneous**). In order that a magnetic field $\mathbf{B}$ may grow, the term on the right-hand side of (3) must overcome the effect of the magnetic diffusion term on the left-hand side. Using a typical velocity U and a typical length scale d , the ratio of the two terms can be estimated by

$$Ud/\lambda \equiv \text{Rm}, \quad (5)$$

which is called the magnetic Reynolds number in analogy to the ordinary Reynolds number used in fluid dynamics. A necessary condition for dynamo action is $\text{Rm} > 1$, but this is by far not a sufficient condition (See **Dynamos, homogeneous**).

A typical problem of MHD is the flow in the channel in the presence of an applied homogeneous magnetic field $\mathbf{B}_0$. The equation for the plane parallel flow $\mathbf{v} = v_x(y)\mathbf{i}$ in the channel between two parallel plates with distance $2d$ is given by

$$\eta \frac{d^2}{dy^2} v_x(y) + \frac{1}{\mu} \mathbf{i} \cdot ((\nabla \times \mathbf{B}) \times \mathbf{B}) = -A, \quad (6)$$

where η is the dynamic viscosity, $\mathbf{i}$ is the unit vector in the x -direction along the channel, and A is the constant pressure gradient in the opposite direction. In accordance with the configuration of the problem, we have assumed that the steady solution depends only on the y -coordinate perpendicular to the plates. Using the

Figure 1. Profile of channel flow for small and large M .

notation $\mathbf{B} = \mathbf{B}_0 + \mathbf{b}$ we find after integrating Equation (4)

$$\lambda \frac{d}{dy} b_x(y) + B_{0y} v_x = -D, \quad (7)$$

where the constant of integration D represents the electric field directed in the z -direction; in other words, Equation (7) is the z -component of Ohm's law. Insertion of this expression into Equation (6) yields

$$\eta \frac{d^2}{dy^2} v_x(y) - \sigma B_{0y}^2 v_x(y) = -A + \sigma B_{0y} D \quad (8)$$

The solution of this equation is given by

$$v_x = v_0 \left(1 - \frac{\cosh(My/d)}{\cosh M} \right), \quad (9)$$

with

$$M \equiv B_{0y} d \sqrt{\sigma/\eta}$$

and

$$v_0 = (A - \sigma D B_{0y}) d^2 / \eta M^2, \quad (10)$$

where M is the Hartmann number named after the scientist who first considered this type of problem. The constant D depends on the boundary condition applied in the transverse z -direction. D can be chosen, for example, such that the average electric current in the z -direction vanishes because of the insulating side walls. It is worth noting that only the y -component of $\mathbf{B}_0$ enters solution (9). The flow is not affected by the x - and z -components of $\mathbf{B}_0$ as long as it does not depend on those coordinates. Depending on the Hartmann number M , the velocity profile $v_x(y)$ varies between the two limiting cases sketched in Figure 1. For $M \rightarrow 0$, the parabolic Poiseuille profile is recovered from expression (9), while for $M \gg 1$, boundary layers of thickness d/M develop, which are called Hartmann layers. In geophysical and astrophysical applications of MHD, the Chandrasekhar number $Q = M^2$ is often used in place of the Hartmann number.

In many applications of MHD, it is justified to neglect magnetic diffusion in first approximation. Then the relationship

$$\frac{\partial}{\partial t} \mathbf{B} = \nabla \times (\mathbf{v} \times \mathbf{B}) \quad (11)$$

can be obtained from Equation (3) in the limit of large magnetic Reynolds numbers. This equation is the same as that obeyed by the vorticity of an inviscid fluid (See **Fluid dynamics**). By analogy to the vorticity laws of

Kelvin and Helmholtz it can be concluded that the field line that is attached to a fluid element at some initial time continues to be attached to that fluid element at all times; that is, the field lines are "frozen" into the fluid. This statement is known as Alfvén's theorem.

In highly electrically conducting fluids, it is appropriate to consider Equation (11) together with the Euler equation of hydrodynamics,

$$\rho \left(\frac{\partial}{\partial t} \mathbf{v} + \mathbf{v} \cdot \nabla \mathbf{v} \right) = -\nabla p + \mu^{-1} (\nabla \times \mathbf{B}) \times \mathbf{B}, \quad (12)$$

where the Lorentz force has been included, but viscous friction has been neglected. In the case of an incompressible fluid with $\rho = \text{constant}$, both, $\mathbf{v}$ and $\mathbf{B}$ are solenoidal vector fields and an exact steady solution of Equations (11) and (12) is given by

$$\mathbf{v} = (\rho\mu)^{-1/2} \mathbf{B}(x, y, z) \quad \text{with} \quad p = p_0 + \rho |\mathbf{v}|^2 / 2, \quad (13)$$

where the relationship $\mathbf{v} \cdot \nabla \mathbf{v} = (\nabla \times \mathbf{v}) \times \mathbf{v} + \nabla |\mathbf{v}|^2 / 2$ has been used. The dependence of $\mathbf{B}$ on the cartesian coordinates x, y, z is arbitrary except for the condition $\nabla \cdot \mathbf{B} = 0$. Let us write $\mathbf{B}$ as the sum of its average and the remainder, $\mathbf{B} = B_0 \mathbf{i} + \mathbf{b}$, where it has been assumed without loss of generality that the average magnetic field is parallel to the x -direction given by the unit vector $\mathbf{i}$. Using a Galileo transformation with the constant velocity vector $V_A \mathbf{i}$, we obtain a time-dependent exact solution relative to the new frame of reference,

$$\mathbf{v}'(x - V_A t, y, z) = (\rho\mu)^{-1/2} \mathbf{b}(x - V_A t, y, z), \quad (14)$$

where the choice $V_A = (\rho\mu)^{-1/2} B_0$ has been made. This solution describes dispersion-free waves called Alfvén waves. The physical interpretation of these waves of arbitrary amplitude is that the field lines of the basic magnetic field are embedded in the fluid-like rubber strings and provide a restoring force whenever a fluid parcel is displaced. The phase velocity V_A is called the Alfvén velocity. In compressible electrically conducting fluids a more complex spectrum of wave phenomena is found owing to combinations of Alfvén and acoustic modes.

MANLEY-ROWE RELATIONS

In lossless linear systems, a harmonic sinusoidal input at a frequency ω remains harmonic, the system's steady-state response to a linear combination of individual harmonic inputs is a linear combination of individual responses, and an average input power is zero at each frequency. In lossless nonlinear systems, on the other hand, harmonic inputs at some frequencies also generate inputs at multiple and combination frequencies. The average input powers at each frequency may not be zero but they are predicted from the general relations found by Jack Manley and Harrison Rowe in 1956 (Manley & Rowe, 1956).

Suppose the input applied to a nonlinear system consists of two harmonic signals of frequencies ω_1 and ω_2 . The nonlinear system produces an output at all frequencies $m\omega_1 + n\omega_2$, where m and n are integers. For example, $m = 2, n = 0$ and $m = 0, n = 2$ are signals at the double frequencies $2\omega_1$ and $2\omega_2$, while $m = n = 1$ a signal with the combinational frequency $\omega_1 + \omega_2$. Denote $P_{m,n}$ the total input power at frequency $m\omega_1 + n\omega_2$. In lossless systems, the total power is zero; thus

$$\sum_{m,n} P_{m,n} = 0.$$

In other words, the power $P_{m,n}$ is negative if the signal at $m\omega_1 + n\omega_2$ is generated due to nonlinearity, and the power is positive if the signal is applied from input to the system.

The Manley-Rowe relations are relations between powers $P_{m,n}$ and frequencies $m\omega_1 + n\omega_2$ (Penfield, 1960):

$$\begin{aligned} \sum_{n=-\infty}^{\infty} \sum_{m=0}^{\infty} \frac{m P_{m,n}}{m\omega_1 + n\omega_2} &= 0, \\ \sum_{m=-\infty}^{\infty} \sum_{n=0}^{\infty} \frac{n P_{m,n}}{m\omega_1 + n\omega_2} &= 0. \end{aligned} \quad (1)$$

As an elementary example, we consider a heterodyne system, comprising an oscillator with frequency ω_1 , which is mixed with the carrier incident frequency ω such that a combination frequency $\omega_2 = \omega - \omega_1$ occurs in the spectrum of the nonlinear system (Scott, 1970). We neglect signals at other frequencies and denote powers at frequencies ω_1 , ω_2 and $\omega = \omega_1 + \omega_2$ as P_1 , P_2 , and $P = -P_1 - P_2$. The Manley-Rowe relations between the powers and frequencies of the three signals are

$$\frac{P_1}{\omega_1} = \frac{P_2}{\omega_2} = -\frac{P}{\omega}$$

Notice that these relations preserve conservation of powers $P_1 + P_2 + P = 0$ at the three resonant frequencies ω_1 , ω_2 , and ω . If $\omega > \omega_1, \omega_2$, the Manley-Rowe relations show that the power P_2 at the combinational frequency ω_2 is smaller than the input power P by a factor of ω_2/ω , while the power at the heterodyne frequency ω_1 is smaller than P by a factor of ω_1/ω . Therefore, when an input signal of larger frequency transforms into output signals of smaller frequencies, the powers of output signals become smaller.

As another application, we consider an electro-optical modulator that takes an input signal at frequency 1 GHz and multiplies with another signal at frequency 100 MHz to produce a modulated output signal at combinational frequency 1.1 GHz. If the power of the output signal has to be 1 mW, the Manley-Rowe relations require powers 0.0909 mW at 100 MHz and 0.9090 mW at 1 GHz. The 1 GHz signal is sometimes called the pump since it provides most of the power needed in the modulation process.

Manley-Rowe relations naturally describe constants of motion in the time evolution of the resonant nonlinear wave interactions. If three waves with frequencies ω_1 , ω_2 and $\omega = \omega_1 + \omega_2$ and wavevectors $\mathbf{k}_1$, $\mathbf{k}_2$ and $\mathbf{k} = \mathbf{k}_1 + \mathbf{k}_2$ satisfy the phase matching conditions

$$\omega(\mathbf{k}_1 + \mathbf{k}_2) = \omega(\mathbf{k}_1) + \omega(\mathbf{k}_2),$$

then their interaction is resonant in time and is described by the system of three-wave interaction equations:

$$\begin{aligned} i \left(\frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla \right) a &= \gamma a_1 a_2 e^{-i\Delta t}, \\ i \left(\frac{\partial}{\partial t} + \mathbf{v}_1 \cdot \nabla \right) a_1 &= \gamma a \bar{a}_2 e^{i\Delta t}, \\ i \left(\frac{\partial}{\partial t} + \mathbf{v}_2 \cdot \nabla \right) a_2 &= \gamma a \bar{a}_1 e^{i\Delta t}, \end{aligned} \quad (2)$$

where $\Delta = \omega(\mathbf{k}) - \omega(\mathbf{k}_1) - \omega(\mathbf{k}_2)$ is the frequency detuning from exact resonance. In other words, $\mathbf{v}$, $\mathbf{v}_1$, and $\mathbf{v}_2$ are group velocities of the three waves, for example, $\mathbf{v} = \nabla \omega(\mathbf{k})$; and γ is a real-valued coupling coefficient in nonlinear systems with quadratic nonlinearities. The system of amplitude equations (2) has integrals of motions:

$$\begin{aligned} Q_1 &= \int (|a|^2 + |a_1|^2) \mathbf{d}\mathbf{x} = \text{const}, \\ Q_2 &= \int (|a|^2 + |a_2|^2) \mathbf{d}\mathbf{x} = \text{const}, \\ Q &= \int (|a_1|^2 - |a_2|^2) \mathbf{d}\mathbf{x} = \text{const}. \end{aligned} \quad (3)$$

The integrals of motions are the Manley–Rowe relations for the powers

$$\begin{aligned} P_1 &= \omega_1 \int |a_1|^2 dx, \\ P_2 &= \omega_2 \int |a_2|^2 dx, \\ P &= \omega \int |a|^2 dx. \end{aligned} \quad (4)$$

The resonant interaction of three waves results in decay of the wave with the larger frequency $\omega > \omega_1, \omega_2$ into waves of smaller frequencies ω_1, ω_2 , which alternates with annihilation of the two waves of smaller frequencies ω_1, ω_2 into the wave of larger frequency ω (Gaponov-Grekhov & Rabinovich, 1992). This process has a simple quantum interpretation. Conservation of quantum momentums and energies of wave particles leads to the resonant relations:

$$\hbar \mathbf{k} = \hbar \mathbf{k}_1 + \hbar \mathbf{k}_2, \quad \hbar \omega = \hbar \omega_1 + \hbar \omega_2,$$

where $\hbar$ is Planck's constant. If the wave of smaller frequency ω_1 is initially larger than the waves of frequencies ω and ω_2 , it cannot decay into the other two waves, because there are not enough wave particles with frequencies ω_2 to merge into wave particles with frequency ω . On the other hand, if the wave of larger frequency ω is initially large, it can decay into two wave particles of smaller frequencies ω_1 and ω_2 . Manley–Rowe relations follow from the conservation of number of particles in the quantum interpretation above. For instance, when a phonon with energy $\hbar \omega$ is absorbed, two phonons of energies $\hbar \omega_1$ and $\hbar \omega_2$ are emitted, such that the Manley–Rowe relations hold.

Manley–Rowe invariants play an important role in studies of properties of three-wave interactions in system (2). In particular, optical solitons are supported by dispersive and diffraction effects in nonlinear three-wave interactions. The stability of optical solitons is determined by the Vakhitov–Kolokolov criterion, which involves derivatives of the Manley–Rowe invariants (3) with respect to parameters of optical solitons (Buryak et al., 1997).

When the frequencies ω_1 and ω_2 of the two resonant waves coincide, the three-wave interactions degenerate into resonant second-harmonic generation; thus the wave $a_1 = a_2 = a_0$ with the fundamental frequency $\omega_1 = \omega_2 = \omega_0$ generates the wave a at the double frequency $\omega = 2\omega_0$. The system of equations (2) simplifies then to the form (Etrich et al., 2000)

$$\begin{aligned} i \left(\frac{\partial}{\partial t} + \mathbf{v}_0 \cdot \nabla \right) a_0 &= \gamma a \bar{a}_0 e^{i\Delta t}, \\ i \left(\frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla \right) a &= \gamma a_0^2 e^{-i\Delta t}. \end{aligned} \quad (5)$$

System (5) for the second-harmonic generation has only one Manley–Rowe invariant:

$$Q_0 = \int (|a_0|^2 + |a|^2) dx = \text{const.}$$

MAPS

A *map* is a dynamical system with discrete time. Such dynamical systems are defined by iterating a transformation ϕ of points $\mathbf{x}$

$$\mathbf{x}_{n+1} = \phi(\mathbf{x}_n), \quad (1)$$

from a space $\mathcal{M}$ of dimension d (or a domain of this space) onto itself. $\mathbf{x}_n$ and $\mathbf{x}_{n+1}$ are thus points belonging to this so-called *phase space* $\mathcal{M}$, which can be a Euclidean space such as the space $\mathbb{R}^d$ of d -tuples of real numbers or a manifold such as a circle, a sphere, or a torus $\mathbb{T}^d$ (or a domain such as an interval or a square).

An *endomorphism* is a surjective (i.e., many-to-one) transformation ϕ of the space $\mathcal{M}$ onto itself. Thus, the transformation ϕ is not invertible. Examples of endomorphisms are one-dimensional maps of the interval such as the logistic map $\phi(x) = 1 - ax^2$ on $-1 \leq x \leq 1$, the Bernoulli map $\phi(x) = rx$ (modulo 1) with integer r (also called *r-adic map*), or the Gauss map $\phi(x) = 1/x$ (modulo 1) which generates continuous fractions. The last two maps are defined onto the unit interval $0 \leq x \leq 1$. There also exist multidimensional examples such as the exact map $\phi(x, y) = (3x + y, x + 3y)$ (modulo 1) on the torus $\mathbb{T}^2$ (Lasota & Mackey, 1985).

An *automorphism* is a one-to-one (i.e., invertible) transformation ϕ of the space $\mathcal{M}$ onto itself. Automorphisms for which the one-to-one

transformation ϕ is continuous on $\mathcal{M}$ are called *homeomorphisms*. We speak about C^r -*diffeomorphisms* if ϕ is r -times differentiable and $\frac{\partial^r \phi}{\partial x^r}$ is continuous on $\mathcal{M}$. Examples of automorphisms are the circle maps defined with a monotonously increasing function $\phi(x) = \phi(x+1) - 1$ onto the circle; the baker map:

$$\phi(x, y) = \begin{cases} (2x, \frac{y}{2}) & \text{if } 0 \leq x < 1/2, \\ (2x - 1, \frac{y+1}{2}) & \text{if } 1/2 \leq x < 1, \end{cases} \quad (2)$$

onto the unit square (Hopf, 1937); the cat map:

$$\phi(x, y) = (x + y, x + 2y) \pmod{1}, \quad (3)$$

onto the torus $\mathbb{T}^2$ (Arnol'd & Avez, 1968); the quadratic map:

$$\phi(x, y) = (y + 1 - ax^2, bx), \quad (4)$$

onto $\mathbb{R}^2$ also called the *Hénon map* (Hénon, 1976; Gumowski & Mira, 1980), among many others.

Iterating a noninvertible transformation ϕ generates a semigroup of endomorphisms $\{\phi^n(\mathbf{x})\}_{n \in \mathbb{N}}$, where $\mathbb{N}$ is the set of nonnegative integers. Iterating an invertible transformation ϕ generates a group of automorphisms $\{\phi^n(\mathbf{x})\}_{n \in \mathbb{Z}}$, where $\mathbb{Z}$ is the set of all the integers. Such groups or semigroups are deterministic dynamical systems with discrete time, called maps.

Link Between Maps and Flows

Maps naturally arise in continuous-time dynamical systems (i.e., flows) defined with $d+1$ ordinary differential equations

$$\frac{d\mathbf{X}}{dt} = \mathbf{F}(\mathbf{X}), \quad (5)$$

by considering the successive intersections of the trajectories $\mathbf{X}(t)$ with a codimension-one Poincaré section $\sigma(\mathbf{X}) = 0$. If $\mathbf{x}$ denotes d coordinates which are intrinsic to the Poincaré section, the successive intersections $\{\mathbf{X}_n = \mathbf{X}(t_n)\}_{n \in \mathbb{Z}}$ of the trajectory correspond to a sequence of points $\{\mathbf{x}_n\}_{n \in \mathbb{Z}}$ and return times $\{t_n\}_{n \in \mathbb{Z}}$ in the Poincaré section. According to Cauchy's theorem which guarantees the unicity of the trajectory $\mathbf{X}(t)$ issued from a given initial condition $\mathbf{X}(0)$ (i.e., by the determinism of the flow), the successive points and return times are related by

$$\begin{cases} \mathbf{x}_{n+1} = \phi(\mathbf{x}_n), \\ t_{n+1} = t_n + T(\mathbf{x}_n), \end{cases} \quad (6)$$

where $\phi(\mathbf{x})$ is the so-called *Poincaré map* and $T(\mathbf{x})$ the return-time (or ceiling) function. The knowledge of the Poincaré map and its associated return-time function allows us to recover the flow and its properties.

Consider a similar construction for ordinary differential equations which are periodic in time

$$\frac{d\mathbf{x}}{dt} = \mathbf{F}(\mathbf{x}, t) = \mathbf{F}(\mathbf{x}, t + T), \quad (7)$$

in which case the return-time function reduces to the period T in Equation (6) and the Poincaré map becomes a *stroboscopic map*.

Examples of Poincaré maps are the Birkhoff maps in the case of billiards. Billiards are systems of particles in free flights (or more generally following Hamiltonian trajectories) interrupted by elastic collisions. The knowledge of the collisions suffices to reconstruct the full trajectories. The Birkhoff map is thus the transformation ruling the dynamics of billiards from collision to collision.

Properties

Maps can be classified according to different properties. An important question is to know if a map is locally volume-preserving or not. If the map is differentiable, the volume preservation holds if the absolute value of its Jacobian determinant is equal to unity everywhere in $\mathcal{M}$:

$$\left| \det \frac{\partial \phi}{\partial \mathbf{x}} \right| = 1. \quad (8)$$

This is the case for the baker map (2), the cat map (3), and the quadratic map (4) if $b = \pm 1$.

Maps that contract phase space volumes on average are said to be *dissipative*. In the limit $b \rightarrow 0$, the two-dimensional automorphism (4) contracts the phase space areas so much that it becomes an endomorphism given by the one-dimensional logistic map. This explains why highly dissipative dynamical systems are often very well described in terms of endomorphisms such as the logistic map.

A map is *symplectic* if its Jacobian matrix satisfies

$$\left(\frac{\partial \phi}{\partial \mathbf{x}} \right)^T \cdot \Sigma \cdot \frac{\partial \phi}{\partial \mathbf{x}} = \Sigma, \quad (9)$$

where T denotes the transpose and Σ is an antisymmetric constant matrix: $\Sigma^T = -\Sigma$. Symplectic maps act onto phase spaces of even dimension. Poincaré maps of Hamiltonian systems as well as Birkhoff maps are symplectic in appropriate coordinates. Symplectic maps are volume-preserving. Area-preserving maps are symplectic, but there exist volume-preserving maps which are not symplectic in dimensions higher than two.

A map is symmetric under a group $\mathcal{G}$ of transformations $\mathbf{g} \in \mathcal{G}$ if

$$\mathbf{g} \circ \phi = \phi \circ \mathbf{g}. \quad (10)$$

A map is said to be *reversible* if there exists an involution, that is, a transformation θ such that $\theta^2 = 1$, which transforms the map into its inverse:

$$\theta \circ \phi \circ \theta = \phi^{-1}. \quad (11)$$

There exist reversible maps which are not volume-preserving (Roberts & Quispel, 1992).

Invariant Subsets

These are subsets of the phase space that are invariant under the action of the map. They include the fixed points $\phi(\mathbf{x}_*) = \mathbf{x}_*$ (which correspond to periodic orbits of a corresponding flow) and the periodic orbits of prime period n defined as trajectories from the initial condition $\mathbf{x}_p$ such that $\phi^n(\mathbf{x}_p) = \mathbf{x}_p$ but $\phi^j(\mathbf{x}_p) \neq \mathbf{x}_p$ for $0 < j < n$. Tori may also be invariant as in the case of KAM quasi-periodic motion.

An invariant subset $\mathcal{I}$ of the map is *attracting* if there exists an open neighborhood $\mathcal{U}$ such that $\phi\mathcal{U} \subset \mathcal{U}$ and $\mathcal{I} = \bigcap_{n \in \mathbb{N}} \phi^n \mathcal{U}$. The open set $\mathcal{B} = \bigcup_{n \in \mathbb{N}} \phi^{-n} \mathcal{U}$ is called the *basin of attraction* of $\mathcal{I}$. An *attractor* is an attracting set which cannot be decomposed into smaller ones. A set which is not attracting is said to be *repelling*.

A closed invariant subset $\mathcal{I}$ is *hyperbolic* if (i) the tangent space $\mathcal{T}_{\mathbf{x}}\mathcal{M}$ of the phase space $\mathcal{M}$ splits into stable and unstable linear subspaces $\mathcal{E}_{\mathbf{x}}^{(s)}$ and $\mathcal{E}_{\mathbf{x}}^{(u)}$ depending continuously on $\mathbf{x} \in \mathcal{I}$,

$$\mathcal{T}_{\mathbf{x}}\mathcal{M} = \mathcal{E}_{\mathbf{x}}^{(s)} \oplus \mathcal{E}_{\mathbf{x}}^{(u)}; \quad (12)$$

(ii) the linearized dynamics preserves these subspaces; and (iii) the vectors of the stable (resp. unstable) subspace are contracted (resp. expanded) by the linearized dynamics (Ott, 1993). Hyperbolicity implies sensitivity to initial conditions of exponential type, characterized by positive Lyapunov exponents. By extension, a map is said to be *hyperbolic* if its invariant subsets are hyperbolic.

For the baker map (2), the unstable linear subspace is the x -direction while the stable one is the y -direction and the unit square is hyperbolic with a positive Lyapunov exponent. Moreover, the dynamics of the baker map can be shown to be equivalent to a so-called Bernoulli shift, that is, a symbolic dynamics acting as a simple shift on all the possible infinite sequences of symbols 0 and 1, so that most of its trajectories are random. The baker map is thus an example of a hyperbolic fully chaotic map.

A diffeomorphism is said to have the *Anosov* property if its whole compact phase space $\mathcal{M}$ is hyperbolic. Examples of Anosov diffeomorphisms are the cat map (3) and its nonlinear perturbations:

$$\begin{cases} x_{n+1} = x_n + y_n + f(x_n, y_n) \pmod{1}, \\ y_{n+1} = x_n + 2y_n + g(x_n, y_n) \pmod{1}, \end{cases} \quad (13)$$

with small enough periodic functions $f(x, y)$ and $g(x, y)$ defined on the torus. We notice that these nonlinear perturbations of the cat map are generally not area-preserving.

Dissipative maps may have chaotic attractors (i.e., attractors with positive Lyapunov exponents) which are not necessarily hyperbolic. This is the case for a set of $a > 0$ values of a positive Lebesgue measure in the logistic map (Jakobson, 1981), as well as in the quadratic map (4) if $b > 0$ is sufficiently small (Benedicks & Carleson, 1991).

Figure 1. Homeomorphisms $y = h(x)$ transforming the dyadic map into maps (15) with $p = 0.1, 0.2, \dots, 0.9$.

Maps may also have sensitivity to initial conditions of stretched-exponential type (with vanishing Lyapunov exponent) as it is the case for the intermittent maps $\phi(x) = x + ax^\zeta$ (modulo 1) with $\zeta > 2$.

Conjugacy Between Maps

In the study of maps, it is often important to modify the analytic form of the map by a change of variables $\mathbf{y} = \mathbf{h}(\mathbf{x})$. Such a conjugacy would transform map (1) into

$$\mathbf{y}_{n+1} = \psi(\mathbf{y}_n), \quad \text{with} \quad \psi = \mathbf{h} \circ \phi \circ \mathbf{h}^{-1}. \quad (14)$$

The Kolmogorov–Sinai entropy per iteration is known to remain invariant if the conjugacy $\mathbf{h}$ is a diffeomorphism, but it is only the topological entropy per iteration which is invariant if the conjugacy is a homeomorphism. For instance, the logistic map $\phi(x) = 1 - 2x^2$ is conjugated to the tent map $\psi(y) = 1 - 2|y|$ by the conjugacy $y = -1 + \frac{4}{\pi} \arcsin \sqrt{\frac{x+1}{2}}$, both maps having their Kolmogorov–Sinai entropy equal to $\ln 2$. On the other hand, the dyadic map $\phi(x) = 2x$ (modulo 1) is conjugated to the map

$$\psi(y) = \begin{cases} \frac{y}{p} & \text{if } 0 \leq y \leq p, \\ \frac{y-p}{1-p} & \text{if } p < y \leq 1, \end{cases} \quad (15)$$

with $p \neq \frac{1}{2}$ by a homeomorphism $h(x)$ which is not differentiable (see Figure 1). These two maps have their topological entropy equal to $\ln 2$ but different Kolmogorov–Sinai entropies.

Conjugacies are also important to transform a circle map such as $\phi(x) = x + \alpha + \varepsilon \sin(2\pi x)$ with $|\varepsilon| < \frac{1}{2\pi}$ into a pure rotation $\psi(y) = y + \omega$ of rotation number

$$\omega = \lim_{n \rightarrow \infty} \frac{1}{n} (x_n - x_0). \quad (16)$$

According to Denjoy theory, such a conjugacy is possible if the rotation number is irrational, in which

case the motion is quasi-periodic and nonchaotic. The circle map also illustrates the phenomenon of synchronization to the external frequency α , which occurs when the rotation number ω takes rational values corresponding to periodic motions. The motion may become chaotic if $|\varepsilon| > \frac{1}{2\pi}$.

Area-preserving Maps

Periodic, quasi-periodic, and chaotic motions are also the features of area-preserving maps which can be considered as Poincaré maps of Hamiltonian systems with two degrees of freedom. Area-preserving maps can be derived from a variational principle based on some Lagrangian generating function $\ell(x_{n+1}, x_n)$. The variational principle requires that the trajectories are extremals of the action

$$W = \sum_{n \in \mathbb{Z}} \ell(x_{n+1}, x_n). \tag{17}$$

The vanishing of the first variation, $\delta W = 0$, leads to the second-order recurrence equation

$$\frac{\partial \ell(x_{n+1}, x_n)}{\partial x_n} + \frac{\partial \ell(x_n, x_{n-1})}{\partial x_n} = 0. \tag{18}$$

This recurrence can be rewritten in the form of a two-dimensional map by expliciting the equations for the momenta

$$\begin{cases} p_{n+1} = \frac{\partial \ell(x_{n+1}, x_n)}{\partial x_{n+1}}, \\ p_n = -\frac{\partial \ell(x_{n+1}, x_n)}{\partial x_n}. \end{cases} \tag{19}$$

The Birkhoff map of a billiard is recovered if ℓ is the distance traveled by the particle in free flight between collisions and x_n is the arc of the perimeter at which the collision occurs. If a free particle or rotor is periodically kicked by an external driving, the Lagrangian function takes the form

$$\ell = \frac{1}{2}(x_{n+1} - x_n)^2 - V(x_n). \tag{20}$$

A famous map is the so-called *standard map*

$$\begin{cases} p_{n+1} = p_n + K \sin x_n, \\ x_{n+1} = x_n + p_{n+1} \pmod{2\pi}, \end{cases} \tag{21}$$

obtained for the kicked rotor with the potential $V(x) = K \cos x$ in Equation (20). The motivation for studying the standard map goes back to works on the origin of stochasticity in Hamiltonian systems (Chirikov, 1979; Lichtenberg & Lieberman, 1983, MacKay & Meiss, 1987).

Phase portraits of an area-preserving map typically present closed curves of KAM quasi-periodic motion, which form elliptic islands. Hierarchical structures of elliptic islands develop on smaller and smaller scales. The elliptic islands are surrounded by chaotic zones extending over finite area (see Figure 2).

Figure 2. Phase portrait of the Fermi-Ulam area-preserving map, $p_{n+1} = |p_n + \sin x_n|$, $x_{n+1} = x_n + 2\pi M/p_{n+1}$ (modulo 2π), ruling the motion of a ball bouncing between a fixed wall and a moving wall oscillating sinusoidally in time, in the limit where the amplitude of the oscillations is much smaller than the distance between the walls. p is the velocity of the ball in units proportional to the maximum velocity of the moving wall. x is the phase of the moving wall at the time of collision. The parameter M is proportional to the ratio of the distance between the walls to the amplitude of the oscillations of the moving wall. (See Lichtenberg & Lieberman, 1983, for more details.)

Typical area-preserving maps such as the standard map (21) or the one of Figure 2 display a variety of motions that interpolate between two extremes, namely, the fully chaotic behavior of hyperbolic area-preserving maps such as the baker and cat maps and the fully regular motion of integrable maps such as the one given by the second-order recurrence:

$$x_{n+1} - 2x_n + x_{n-1} = -2i \ln \frac{\kappa^2 + e^{-ix_n}}{\kappa^2 + e^{+ix_n}} \tag{22}$$

(Faddeev & Volkov, 1994).

Some area-preserving maps may have a repelling Smale horseshoe as the only invariant subset at finite distance. This is the case in the quadratic map (4) for $b = -1$ and large enough values of $a > 0$. Such horseshoes often arise in open two-degrees-of-freedom Hamiltonian systems describing the chaotic scattering of a particle in some time-periodic potential.

Complex Maps

Such maps are defined with some analytic function $\phi(z)$ of $z = x + iy \in \mathbb{C}$ or some multidimensional generalizations of it. Complex maps are generally endomorphisms. An example is the complex logistic map $\phi(z) = z^2 + c$. Other examples are given by the Newton-Raphson method of finding the roots of a

function $f(z) = 0$:

$$z_{n+1} = z_n - \frac{f(z_n)}{f'(z_n)}. \tag{23}$$

Complex maps have invariant subsets called Julia sets which are defined as the closure of the set of repelling periodic orbits (Devaney, 1986). The motion is typically chaotic on the Julia set which is repelling and often separates the basins of attraction of the attractors. For instance, the map

$$z_{n+1} = \frac{z_n}{2} + \frac{1}{2z_n}, \tag{24}$$

derived from Equation (23) with $f(z) = z^2 - 1$ has the attractors $z = \pm 1$. Their respective basins of attraction $x > 0$ and $x < 0$ are separated by the line $x = 0$ where the dynamics is ruled by Equation (24) with $z = iy$. This one-dimensional map is conjugated to the dyadic map

$$\chi_{n+1} = \begin{cases} 2\chi_n - \frac{\pi}{2} & \text{if } 0 \leq \chi_n \leq \frac{\pi}{2}, \\ 2\chi_n + \frac{\pi}{2} & \text{if } -\frac{\pi}{2} < \chi_n \leq 0, \end{cases} \tag{25}$$

by the transformation $y = \tan \chi$, which shows that the dynamics is chaotic on this Julia set.

However, the boundaries between the basins of attraction are typically fractal (Ott, 1993) as is the case for the Newton–Raphson map (23) with $f(z) = e^z - 1$ (see Figure 3).

Maps and Probability

An important issue is to understand how maps evolve probability in their phase space. The time evolution of probability densities is ruled by the so-called Frobenius–Perron equation (Lasota & Mackey, 1985). The probability density at the current point $\mathbf{x}$ comes from all the points $\mathbf{y}$ that are mapped

onto $\mathbf{x}$. Since the inverse of an endomorphism is not unique, the Frobenius–Perron equation is composed of the sum

$$\rho_{n+1}(\mathbf{x}) = \sum_{\mathbf{y}: \phi(\mathbf{y})=\mathbf{x}} \left| \frac{\rho_n(\mathbf{y})}{\det \frac{\partial \phi}{\partial \mathbf{x}}(\mathbf{y})} \right|. \tag{26}$$

For an automorphism, the sum reduces to the single term corresponding to the unique inverse. An invariant probability measure is obtained as a solution of the Frobenius–Perron equation such that $\rho_{n+1}(\mathbf{x}) = \rho_n(\mathbf{x})$. The study of invariant measures is the subject of ergodic theory (Hopf, 1937; Arnol’d & Avez, 1968; Cornfeld et al., 1982). The knowledge of the ergodic invariant measure provides us with the statistics of the quantities of interest: observables, correlation functions, Lyapunov exponents, the Kolmogorov–Sinai entropy, etc. With these tools, transport properties such as normal and anomalous diffusion can also be studied in maps (Lichtenberg & Lieberman, 1983).

Some Applications

Dissipative maps are used to study chaos in hydrodynamics (Lorenz, 1963), chemical kinetics (Scott, 1991), biology (Olsen & Degn, 1985; Murray, 1993), nonlinear optics (Ikeda et al., 1980), and more. In particular, systems with time delay in some feedback can be approximated by maps, as in the nonlinear optics of a ring cavity (see Figure 4).

Dissipative maps are also used to study complex systems composed of many interacting units. The units may form a lattice or a graph and interact with each other by diffusive or global couplings. These high-dimensional maps are often called *coupled map lattices* in reference to their spatial extension.

Figure 3. Complex map $z_{n+1} = z_n - 1 + \exp(-z_n)$: basin of attraction of the point at infinity in grey and of the attractors $z = 0, \pm 2\pi i, \pm 4\pi i, \dots$ in white. The dot is the attractor $z = 0$.

Figure 4. Chaotic attractor of the dissipative Ikeda map $E_{n+1} = a + bE_n \exp(i|E_n|^2 - ic)$ ruling the complex amplitude $E_n \in \mathbb{C}$ of the electric field of light transmitted in a ring cavity containing a nonlinear dielectric medium, at each passage along the ring (Ikeda et al., 1980). The parameters take the values $a = 3.9$, $b = 0.5$, and $c = 1$.

In addition, area-preserving and symplectic maps have become a fundamental tool to study the long-term evolution of the Solar system (Murray & Dermott, 1999).

MAPS IN THE COMPLEX PLANE

Iterates of rational functions in the complex plane form a class of dynamical systems that can be characterized in amazing detail and completeness. Gaston Julia (1918) and Pierre Fatou (1919/20) proved fundamental theorems on the invariant sets and the relation between critical points and attracting cycles. In some of the first numerical studies of the iterates of a quadratic polynomial, Benoit Mandelbrot discovered the set now named after him (Mandelbrot, 1980). Dennis Sullivan (1985) proved the complete classification of attractors and Adrien Douady & John Hubbard (1984) showed that the Mandelbrot set is connected. Because of their aesthetic beauty, their intricate details, and their omnipresence in iterations of complex functions, Mandelbrot and Julia sets belong to the most fascinating and most widely studied fractal objects. The book by Richter & Peitgen (1986) contains a good survey of the results and many color plates of Julia sets and Mandelbrot sets, as well as personal reflections by Mandelbrot and Douady.

In order to illustrate some of the ideas and concepts, consider the rational maps that result from Newton’s method for roots of polynomials (Curry et al., 1983). Their roots can be found using Newton’s method, where an initial point z_0 is iterated according to the rational map

$$z_{n+1} = g(z_n) = z_n - f(z_n)/f'(z_n). \quad (1)$$

For initial conditions sufficiently close to a root, the method converges faster than quadratically, hence its popularity in numerical mathematics. But a little numerical exploration shows that when the initial condition is further away from a root, the iterations can behave rather unpredictably.

Helpful for the investigation of the global dynamics of the iterates is a theorem due to Fatou (1919/20), according to which any attracting cycle will have a critical point in its basin of attraction. A point x_p on a cycle of period k returns after k iterations to its starting point, $z_p = g^{(k)}(z_p)$. At a critical point the derivative vanishes, $g'(z_c) = 0$. Newton’s method for polynomials has $g'(z) = f(z)f''(z)/(f'(z))^2$; therefore, the critical points include the roots of the polynomial and the inflection points where $f''(z_c) = 0$. Since the roots of the polynomials are at the same time fixed points and critical points for Newton’s method, each one of them is attracting. It thus suffices to investigate the dynamics of the inflection points.

Points that do not iterate to a root or to any other attracting object form the Julia set.

In 1879, Arthur Cayley solved the simplest case, Newton’s method for the quadratic polynomial $z^2 - 1 = 0$, where the iteration reads

$$z_{n+1} = \frac{z_n^2 + 1}{2z_n}. \quad (2)$$

Figure 1. Initial conditions in Newton's method that converge to the root at 1 for the cubic equation $z^3 = 1$. The initial conditions for the other roots follow from symmetry by rotation through an angle of $\pm 2\pi/3$ around the origin.

There are no critical points besides the roots and hence no other attracting regions. The imaginary axis is the Julia set: it is mapped into itself and is the border between the two domains of attraction.

At the end of his paper Cayley comments that "the next succeeding case of the cubic equation appears to present considerable difficulty". Just how difficult is indicated in Figure 1 for the case $f(z) = z^3 - 1$. Evidently, not only the immediate neighborhood of 1 but also many points further away will map into the root $z_0 = 1$. The critical point $z_c = 0$ is mapped to infinity, so that there are no other attractors. The boundary of the black region is the Julia set. It has the interesting feature that in an arbitrarily small neighborhood of every point, initial conditions can be found that iterate to any one of the possible roots. That is to say, at a boundary point, the attracting regions for all roots, and not just for two roots, meet. It has self-similar and fractal features (for instance, its Hausdorff dimension is about 1.429... (Nauenberg & Schellnhuber, 1989)), but it is not of full measure.

For more general third-order polynomials, for example,

$$p_a(z) = z^3 + (a - 1)z - a, \quad (3)$$

it can happen that a set of initial conditions of finite measure will not converge to any one of the roots (Curry et al., 1983). Then the iterates of the critical point $z_c = 0$ remain bounded but do not approach a root. For instance, for the parameter values underlying Figure 2, the critical point maps into a period-2 cycle. For initial conditions in the set shown, Newton's method will not find a root; instead, it will converge to a cycle of period 2.

Concerning the dependence on the parameter a , one can map out regions in the parameter space where the critical point $z_c = 0$ does not iterate toward one of the roots or to infinity: for parameter a inside the black region in Figure 3, it approaches another attracting set and Newton's method fails. Besides the case of an attracting cycle of period 2 as in Figure 2, with parameters from the main cardioid of the set, one can find cycles of period 4 in the circular bud to the left, of period 8 even further to the left, and so on: the attracting periodic orbit undergoes period doubling. For parameters in other parts of the set, other sequences of bifurcations occur.

The object that appears in Figure 3 was first seen by Benoit Mandelbrot (1980) in investigations of iterates of the family of quadratic polynomials

$$z_{n+1} = z_n^2 + c. \quad (4)$$

This map has only one critical point, $z_c = 0$. For points outside the Mandelbrot set z_c iterates to infinity and there are no stable attracting cycles. The different compartments and regions inside the Mandelbrot set then contain parameter values where different cycles are stable, and transitions between regions correspond to various bifurcations. The cycles that are not attracting are dense in the Julia sets. For parameter values inside the Mandelbrot set, the Julia set is connected; for parameters outside, it dissolves into a Fatou dust. For $c = 0$, the Julia set is a circle of dimension 1, and for small $c \neq 0$, it becomes a fractal with dimension

$$d \approx 1 + \frac{|c|^2}{4 \ln 2} \quad \text{for small } c. \quad (5)$$

For real parameters and real z_n , the map belongs to the class of unimodal maps with quadratic maxima for which the period doubling cascade with its universal scaling laws in parameter and distance between periodic points applies. These relations then translate into scalings of the diameters of the buds in the Mandelbrot set and of structures in the Julia set. A fairly complete description of the structures in both the Mandelbrot set and the associated Julia sets can be achieved using methods from conformal mappings (Douady & Hubbard, 1984/85).

The previous examples already illustrate several kinds of behaviors of iterates. They can map to a fixed point of a periodic orbit, in which case the orbit is stable; if the derivative $M_p = dg^{(k)}(x_p)/dx_p$ along the orbit vanishes, as in the case of the roots for Newton's method, the orbit is superstable. Orbits that have derivatives $|M_p| > 1$ are repelling and belong to the Julia set. To complete the classification of all possible attractors as given by Sullivan (1985), we need to add the marginal cases when the derivative is of modulus one, $M_p = \exp(2\pi\alpha)$: such orbits are called rationally or irrationally indifferent for rational and irrational α , respectively. Near irrationally indifferent

Figure 2. Initial conditions in Newton's method that do not converge to any one of the roots for the cubic polynomial (3) with parameter $a = 0.32 + 1.64i$. In the big blobs initial conditions converge to a period two cycle.

Figure 3. An example of the set of parameters a for which the iterates of the critical points for Newton's method for polynomial (3) do not approach one of the roots. In the main cardioid, the iterates approach a stable period 2 orbit, and in the buds attached to the main cardioid other orbits of higher period are stable. The small speckles outside the main object are also part of the Mandelbrot set that are connected to it by thin hairs and filaments which are not resolved in this plot.

orbits, Siegel disks, and Herman rings can appear. Sullivan's classification theorem now states that there are countably many attracting regions and that they can belong to superstable orbits, stable orbits, Siegel disks, or Herman rings. They can be identified by following iterates of critical points which will bring one to the attracting orbit or to the boundaries for the irrationally indifferent regions.

MARKIN-CHIZMADZHEV MODEL

The Hodgkin & Huxley (1952) equations provide a quantitatively accurate and detailed model of the currents generating the propagating nerve impulse in the squid giant axon, and as the first such model they formed a prototype for nerve excitation. The equations are nonlinear, with four dynamical variables, and are in the form of a reaction-diffusion partial differential equation. Thus, the model is analytically intractable and numerical solution—now a trivial task on a PC—in the 1960s, required mainframe facilities. Simpler models were needed, both for understanding the mechanisms of propagation, and numerical exploration of propagation; such simple models are still used to simulate propagation in the anisotropic geometry of cardiac muscle (Panfilov, 1997). One approach is the FitzHugh-Nagumo equations, in which the nonlinear current-voltage relation of excitable membranes is caricatured by a cubic function (Rinzel & Keller, 1973). Another approach is to directly specify the currents flowing during the action potential.

Starting with the nonlinear cable equation for a nonmyelinated axon with axoplasmic resistance R and membrane capacitance C (both per unit length of axon), spread of membrane potential V with distance x (cm) and time t (ms) is described by

$$C \frac{\partial V}{\partial t} = \frac{1}{R} \frac{\partial^2 V}{\partial x^2} - I_{\text{ion}}, \quad (1)$$

where I_{ion} is a nonlinear function of V and t . Markin & Chizmadzhev (1967) assumed the following simple form for the membrane ionic current I_{ion} . This current was assumed to be switched to a constant inward current J_1 at the start of excitation and, after a time τ_1 , switched to a smaller, longer constant outward current J_2 for a time period τ_2 . The nonlinear diffusion equation (1) is thus replaced by a piecewise linear diffusion equation. Considering a solitary traveling-wave solution with a velocity θ ms^{-1} , moving to the coordinate system $\xi = x - \theta t$ reduces Equation (1) to an autonomous ordinary differential equation

$$\frac{\partial^2 V}{\partial \xi^2} + \theta RC \frac{\partial V}{\partial \xi} - RI(\xi) = 0. \quad (2)$$

For the Markin-Chizmadzhev model, I_{ion} in Equation (2) is linear in the four regions: (i) $\xi > 0$, (ii) $0 > \xi > -\theta\tau_1$, (iii) $-\theta\tau_1 > \xi > -\theta(\tau_1 + \tau_2)$, and (iv) $\xi < -\theta(\tau_1 + \tau_2)$, so the traveling-wave solution can be constructed analytically from four components, as shown in Figure 1.

Analytic estimates for the velocities of the two traveling wave solutions, the larger being faster and stable, were obtained, these being analogous to earlier numerical studies on propagating activity of the Hodgkin-Huxley equations. This simple Markin-Chizmadzhev model for the membrane current generator retains the ratio of inward to outward current magnitudes and

Figure 1. (a) Assumed membrane current and (b) computed potential during a solitary propagating action potential for the Markin-Chizmadzhev model for a nonmyelinated axon, with propagation velocity θ .

the relative time courses of the inward and outward membrane currents. A greater simplification is to consider the action potential as an event that is produced whenever a threshold is exceeded. Such an approach is widely used in modeling periodic and stochastic spike trains, for example, by the integrate and fire model.

Markin et al. (1987) apply the membrane current generator model to provide estimates for the effects of branching and changes in axonal diameter on propagation, and the interaction between propagating activity in axons forming nerve trunks, where extracellular conduction pathways allow the possibility of ephaptic transmission (an action potential in one fiber inducing changes in potential in neighboring fibers), and an increased synchronization of propagating activity in a bundle of nerve fibers. They also applied the model to propagation of activity in syncytia—branching networks of coupled cells. The spread of excitation in such systems depends on the relative cell sizes and connections (it is easier for a large cell to excite a smaller adjacent cell). For systems of similar cells, the syncytium merges into an excitable medium as the cell-to-cell coupling is increased. Such excitable media models are widely used to model propagation in cardiac tissue.

A behavior of excitable media in which a drifting source emits periodic waves was believed to be associated with macroscopic inhomogeneities. Markin & Chizmadzhev (1972) showed that in two homogeneous coupled one-dimensional fibers, activity propagating

along one can excite activity in the other and vice-versa, setting up a reverberator that acts as a drifting source of periodic wave trains in a homogeneous system whose components all have stable equilibrium solutions. This provides a prototype, with two coupled one-dimensional fibers, for re-entry, which in two-dimensional excitable media appears as a spiral wave.

The basic phenomenology of propagation in excitable media was first studied with the Markin-Chizmadzhev model, as it allowed both piecewise linear analysis and rapid numerical solution. There is still a need for simple models for rapid simulation in three-dimensional media, but the Markin-Chizmadzhev model has been superseded by an efficient two-variable system for excitable media in general (Dowle et al., 1997), and the Fenton-Karma (1998) three current model for cardiac tissue.

MARKOV CHAIN

See **Stochastic processes**

MARKOV PARTITIONS

To simplify analysis of a dynamical system, we often study a topologically equivalent system using symbolic

dynamics, representing trajectories by infinite length sequences using a finite number of symbols. (A simple example of this idea is the writing of real numbers as sequences of digits, a finite collection of symbols.) To represent the state space of a dynamical system with a finite number of symbols, we must partition the space into a finite number of elements and assign a symbol to each one.

Definition. A topological partition of a metric space M is a finite collection $\mathcal{P} = \{P_1, P_2, \dots, P_r\}$ of disjoint open sets whose closures cover M in the sense that $M = \bar{P}_1 \cup \dots \cup \bar{P}_r$ (Lind & Marcus, 1995).

In probability theory, the term Markov denotes memorylessness. In other words, the probability of each outcome conditioned on all previous history is equal to conditioning only on the current state; no previous history is necessary. The same idea has been adapted to the dynamical systems theory to denote a partitioning of the state space so that all of the past information in the symbol sequence is contained in the current symbol, giving rise to the idea of a Markov transformation.

One-dimensional Transformations

In the special, but important case that a transformation of the interval is Markov, the symbolic dynamic is simply presented as a finite directed graph. A Markov transformation in $\mathcal{R}^1$ is defined as follows (Góra & Boyarsky, 1997):

Definition. Let $I = [c, d]$ and let $\tau: I \rightarrow I$. Let $\mathcal{P}$ be a partition of I given by the points $c = c_0 < c_1 < \dots < c_p = d$. For $i = 1, \dots, p$, let $I_i = (c_{i-1}, c_i)$ and denote the restriction of τ to I_i by τ_i . If τ_i is a homeomorphism from I_i onto a union of intervals of $\mathcal{P}$, then τ is said to be Markov. The partition $\mathcal{P}$ is said to be a Markov partition with respect to the function τ .

There are two key elements of the Markov partition that allow the symbol dynamics to accurately represent the system. First, on each interval I_i of the partition, the map must be monotonic (a homeomorphism), which ensures that whenever the preimage of a point is inside an interval, the preimage is unique. Second, whenever the image of a partition element intersects another element, it covers that interval. Therefore, regardless of the trajectory before entering an interval I_j , the orbit may follow any allowed trajectory from I_j . (The future evolves only from the present state.)

As a one-dimensional example, consider map 1 (Figure 1a) which is a Markov map with the associated partition $\{I_1, I_2, I_3, I_4\}$. The symbol dynamics are captured by the transition graph (Figure 1b). Although map 2 (Figure 1c) is piecewise linear and is logically

Figure 1. (a) A Markov map with partition shown. Note that on each interval, the map is a one-to-one and the image of the interval covers every interval that it intersects. (b) The transition graph for map 1. (c) The partition is not Markov ("Bad"): the image of I_2 stretches into interval I_3 , but it does not completely cover that interval (and similarly for the image of I_3 with I_4).

partitioned by the same intervals as map 1, the partition is not Markov because interval I_2 does not map onto (in the mathematical sense) a union of any of the intervals of the partition. However, we are not able to say that map 2 is not Markov. There may be some other partition that satisfies the Markov condition. In general, finding a Markov partition or proving that such a partition does not exist is a difficult problem.

Higher Dimensions

Any topological partitioning of the state space will create symbol dynamics for the map. In the special case where the partition is Markov, the symbol dynamics capture the essential dynamics of the original system.

Definition. Given a metric space M and a map $f: M \rightarrow M$, a Markov partition of M is a topological partition of M into rectangles $\{R_1, \dots, R_m\}$ such that whenever $x \in R_i$ and $f(x) \in R_j$, then (Bowen, 1975; Guckenheimer & Holmes, 1983)

$$f[W^u(x) \cap R_i] \supset W_u[f(x)] \cap R_j$$

and

$$f[W^s(x) \cap R_i] \subset W_s[f(x)] \cap R_j. \quad (1)$$

To determine if the partition is Markov, in other words, we find the stable and unstable manifolds (W^s and W^u) of each point x and its image $f(x)$, and consider the restriction of these manifolds to the partition rectangles. Thus, whenever an image rectangle intersects a partition element, the image must stretch completely across that element in the expanding (unstable) directions, but the image must be inside that partition element in the contracting (stable) direction. (See Figure 2.)

It is important to use a "good" partition so that the resulting symbolic dynamics of orbits through the partition well represents the dynamical system. If the partition is Markov, then goodness is most easily ensured. However, a broader notion, called generating partition, may be necessary to capture the dynamics. A Markov partition is generating, but the converse is not generally true. See Boltt et al. (2001) and Rudolph

Figure 2. In the unstable (expanding) direction, the image rectangle must stretch completely across any of the partition rectangles that it intersects.

Figure 3. The cat map is a toral automorphism. (a) The operation of the linear map on the unit square. (b) Under the mod operation, the image is exactly the unit square. (c) Tessellation by rectangles R_1 and R_2 forms an infinite partition on $\mathbf{R}^2$. However, since the map is defined on the toral space $\mathbf{T}^2$, only two rectangles are required to cover the space. The filled gray boxes illustrate that R_1 and R_2 are mapped completely across a union of rectangles.

(1990) for a discussion of the role of partitions in representing dynamical systems.

The cat map, defined by

$$\mathbf{x} = (A\mathbf{x}) \bmod 1, \quad (2)$$

where

$$A = \begin{bmatrix} 2 & 1 \\ 1 & 1 \end{bmatrix} \quad (3)$$

yields a map from the unit square onto itself. This map is said to be on the toral space $\mathbf{T}^2$ because the mod 1 operation causes the coordinate $1 + z$ to be equivalent to z . A Markov partition for this map is shown in Figure 3 (see also color plate section). The cat map is part of a larger class of functions called toral Anosov diffeomorphisms and provides a detailed description of how to construct Markov partitions for this class of maps (Robinson, 1995).

Applications

In addition to establishing the link to symbol dynamics, the Markov partition has another direct application in the one-dimensional case. In a dynamical system, we are often interested in the overall behavior of the map—the evolution of an ensemble of initial conditions. The Frobenius–Perron operator is used to describe this evolution. When the map is Markov, this operator reduces to finite-dimensional stochastic transition matrix. Following the same development as in probability theory, the stationary (invariant) density associated with these maps is described by the eigenvector for the eigenvalue $\lambda = 1$. If the system

meets certain ergodic conditions, this density will describe the time average behavior of the system.

The analysis of the ensemble behavior of a dynamical system via its transition matrix is such a powerful tool that we would like to apply it to other one-dimensional systems, even when they may not be Markov. A general technique for approximating the invariant density of a map is called Ulam's method, conjectured by Ulam in 1960 and later proven by Li in 1976. The method relies upon the fact that Markov maps are dense in function space (Froyland, 2000).

MARTINGALES

The classic setting for probability is that of independent random variables. An experiment is repeated many times, and whatever happens in one trial has no effect on what happens in future trials. However, many results of probability also hold true in a much more general setting, that of martingales. The word *martingale* is associated with the concept of a gambling scheme, but its importance in probability is quite general and goes far beyond gambling. The reason is that it is rather easy to find or construct martingales, and these give useful insights into probability problems.

In roulette, the “martingale system” is to double the bet (on black or red) after each bet, until one finally

wins. (See Example 4.) The word *martingale* is also used for various arrangements of constraints: part of a horse's reins, lines controlling the jib of a yacht, and the belt at the back of a jacket. The word has been traced back to Middle French before 1600 and, in some accounts, comes from the town of Martigues, presumably a center for horses and gambling.

Definition

The mathematical definition of a martingale involves conditional expectation, and this is a nonlinear concept. If $X_1, \dots, X_n$ are random variables, then they generate a larger set $\mathcal{F}_n$ of random variables. This set $\mathcal{F}_n$ is defined as the set of all random variables W such that there exists a function f (possibly very nonlinear) with $W = f(X_1, \dots, X_n)$. If Z is a real random variable with well-defined expectation $E[Z]$, then the “conditional expectation” $E[Z | \mathcal{F}_n] = h(X_1, \dots, X_n)$ is an element of $\mathcal{F}_n$. It is determined by the condition that for every bounded random variable W in $\mathcal{F}_n$ we have $E[E[Z | \mathcal{F}_n] W] = E[Z W]$. In other words, $E[Z | \mathcal{F}_n]$ is the orthogonal projection of Z onto the nonlinearly generated space $\mathcal{F}_n$.

A martingale is a fair game at each step. (There is also a concept of supermartingale, an unfavorable game, and a corresponding concept of submartingale, a favorable game. These are discussed in the references.) Thus, a martingale is a sequence of random variables S_n , one for each time step. These represent the fortune of the gambler at time n . Let $\mathcal{F}_n$ be generated by the random variables that are defined by what happens up to and including time n . Thus, in particular S_n belongs to $\mathcal{F}_n$. However, the fortune S_{n+1} at the next time step typically does not belong to $\mathcal{F}_n$. Past history does not determine future performance.

The martingale condition is that the conditional expectation $E[S_{n+1} | \mathcal{F}_n] = S_n$. That is, given the past history up to time n , the expected change in fortune at the next step into the future is zero. It follows easily that the expected fortune $E[S_n]$ does not depend on n and is equal to $E[S_0]$.

A long-held dream of gamblers was to find a gambling scheme to play a fair game and win on the average. The situation is clarified by the following theorems. The dream can be realized, but only if one ignores constraints on time and capital.

Theorems and Examples

Some theorems involving martingales and examples are as follows.

Theorem. A martingale that is bounded above or bounded below must converge almost surely. Thus there is a random variable S_∞ such that $S_n \rightarrow S_\infty$ as $n \rightarrow \infty$ with probability one.

Theorem. A martingale that is bounded above and below is fair in the limit. That is, $E[S_\infty] = E[S_0]$.

Example 1. Symmetric random walk. A symmetric random walk is obtained by starting with zero and then making each future step equal to $+1$ or -1 , each independently with probability $\frac{1}{2}$. The walk is the sum of the steps. This is a martingale. In fact, it is a sum of independent random variables. It is unbounded above and below, and it does not converge.

Example 2. Stop when ahead. Consider an integer b with $0 < b$. When the random walk first reaches b , make every future step equal to 0. Notice that these future steps are not independent of the past steps. This is a martingale. At each stage it is a fair game. There is no possibility of winning more than b , but one can be very far in debt. Since this martingale is bounded above, it must converge almost surely, and it can only converge to the constant value b . Thus, a gambler with unlimited credit and unlimited time can play a fair game and be almost sure to win a fixed specified amount.

Example 3. Stop when ahead or behind. Let $a < 0 < b$. When the random walk first reaches a or b , make every future step equal to 0. This is a martingale. It is bounded both above and below. This martingale converges almost surely to a random value that is either a or b . Furthermore, the expected value of the eventual winnings is zero.

Example 4. Double the bet and stop when ahead. The first step is ± 1 as before. For a while, each future step is either positive or negative with equal probability, but twice the size of the previous step. After the first positive step, future steps are zero. Thus, for example, the first steps might be $-1, -2, -4, -8, +16$. The result is that the gambler is ahead by one. This is again a martingale. Since it is bounded above, it converges almost surely to 1. This is favorable to the gambler.

Example 5. Double the bet, start again when ahead. The strategy is the same as in the previous example. However, once the gambler is ahead by one, the game is repeated until the gambler is ahead by two. Then it is repeated again, and so on. This too is a martingale. It has the remarkable property that it diverges almost surely to $+\infty$.

The same ideas may be formulated via the concept of martingale difference. Let $X_0, X_1, X_2, \dots, X_n, \dots$ be a sequence of random variables. This is a stochastic process with a discrete time index. (Most of the concepts discussed below extend to continuous time stochastic processes, but this generalization is left to the references.) Let $\mathcal{F}_n$ be the set of all random variables $f(X_0, X_1, X_2, \dots, X_n)$ that are functions of $X_0, \dots, X_n$. A sequence of real random variables Y_n belonging to $\mathcal{F}_n$ is called a “martingale difference” if

for each $n \geq 0$ the conditional expectation

$$E[Y_{n+1} \mid \mathcal{F}_n] = 0. \quad (1)$$

It is easy to see that if S_0 is in $\mathcal{F}_0$ and the Y_n form a martingale difference, then the sum $S_n = S_0 + Y_1 + Y_2 + \dots + Y_n$ is a martingale.

The advantage of martingales is that they are easy to create. One general method is to produce martingale differences by subtracting conditional expectations. Thus, if each Z_n is in $\mathcal{F}_n$, then

$$Y_{n+1} = Z_{n+1} - E[Z_{n+1} \mid \mathcal{F}_n] \quad (2)$$

is a martingale difference. However, it is also possible to create martingales by other natural constructions, as shown by the following examples.

Example 6. A branching process. Start with W_0 individuals at stage 0. At each stage n there are W_n individuals. The j th individual in the n th generation has $X_j^{(n+1)}$ children, independently of all other individuals. This number of children is random with expectation $\mu > 0$. Thus the $n+1$ th generation has

$$W_{n+1} = X_1^{(n+1)} + \dots + X_{W_n}^{(n+1)} \quad (3)$$

individuals. Since

$$E[W_{n+1} \mid \mathcal{F}_n] = \mu W_n, \quad (4)$$

the sequence $S_n = W_n / \mu^n$ is a martingale. In particular, the expected size of the n th generation is

$$E[W_n] = \mu^n E[W_0]. \quad (5)$$

However, this average behavior gives a rather misleading picture of the branching process. The martingale S_n is bounded below by zero, and so it converges to some random value S_∞ almost surely. When $\mu \leq 1$, then the population goes extinct, and so $S_n = W_n / \mu^n \rightarrow 0$ almost surely as $n \rightarrow \infty$. However, in the case $\mu > 1$, it may be shown that the martingale is fair in the limit. Thus $S_n = W_n / \mu^n \rightarrow S_\infty$, where $S_\infty \geq 0$ is random with expectation $E[S_\infty] = E[S_0] = E[W_0]$. If the population does not die out fairly soon, then it has exponential growth: asymptotically $W_n \sim S_\infty \mu^n$.

Example 7. Extinction of a branching process. Let $\mu > 1$ and let ρ be the probability of extinction starting with just one member of the population. Then ρ^{W_n} is a bounded martingale. It converges to 1 when the population goes extinct, and it converges to zero when the population goes to infinity. The fact that it remains fair in the limit says that the probability of extinction starting with w individuals is ρ^w . Each individual's line must die out independently.

Markov Chain Examples

Let $X_0, X_1, X_2, \dots, X_n, \dots$ be a Markov chain. (Continuous time Markov processes may also be treated, but that subject is also left to the references.) Let f be a real function of the state of the chain.

Then the present value $f(X_n)$ is a random variable. By the definition of a Markov chain, the expectation of a future value $f(X_{n+1})$, given the past $\mathcal{F}_n$, generated by $X_0, \dots, X_n$, depends only on the present state X_n . That is,

$$E[f(X_{n+1}) | \mathcal{F}_n] = (Pf)(X_n), \quad (6)$$

where Pf is the application of the transition probability operator to the function f . (One can think of f as a column vector and P as multiplication by a square matrix, so Pf is another column vector.) Thus, in the special case when $Pf = f$, the sequence $f(X_n)$ is a martingale. It depends only on the current state. Such functions f are of particular interest when the chain has transient states that can lead to distinct recurrent classes.

Example 8. Asymmetric random walk (gambler's ruin). Let the Markov chain X_n be the random walk that starts at 0 and steps by +1 with probability p and steps by -1 with probability q , where $p + q = 1$. To be realistic in the gambling situation, take $0 < p < q < 1$. It is easy to check that the modified game $S_n = (q/p)^{X_n}$ is a martingale.

Example 9. Stop when ahead. Let $0 < b$. When the random walk X_n first reaches b , future steps are zero. Then $S_n = (q/p)^{X_n}$ is a bounded martingale. Therefore, it must converge almost surely and remain fair in the limit. The gambler either wins or goes further and further into debt. It follows from the fact that the modified game is fair in the limit that $1 = (q/p)^b P[X_n \rightarrow b]$. Thus, the probability of winning is $P[X_n \rightarrow b] = (p/q)^b$.

Example 10. Stop when ahead or behind. Let $a < 0 < b$. When the random walk X_n first reaches a or b , future steps are zero. It follows that $1 = (q/p)^a P[X_n \rightarrow a] + (q/p)^b P[X_n \rightarrow b]$. From this, it is easy to work out the probabilities of winning or losing. The probability of winning is less than in the last example, but the gambler is protected from catastrophe.

If f is a function of the state of a Markov chain, but $Pf \neq f$, then there is still an associated martingale, but it has a different character. Let

$$Y_{n+1} = f(X_{n+1}) - (Pf)(X_n). \quad (7)$$

Then Y_n forms a martingale difference sequence. Let $S_0 = f(X_0)$ and form the martingale S_n as before. Then the neighboring terms group together, and we get

$$S_n = u(X_0) + u(X_1) + u(X_2) + \dots + u(X_{n-1}) + f(X_n), \quad (8)$$

where $u = f - Pf$. The martingale is a cumulative sum over the entire history.

For this result to be useful, it is necessary to find an interesting function u for which there is a solution f of $u = f - Pf$. This often happens in the context of an irreducible Markov chain with only positive recurrent

states. Let π be the invariant probability vector for the Markov chain. (One can think of π as a row vector satisfying $\pi P = \pi$.) Then a necessary condition for a solution is that $\pi u = 0$. For instance, one can take a function h and define $u = h - (\pi h)1$. If f is bounded, then $f(X_n)/n \rightarrow 0$, and in suitable circumstances the strong law of large numbers for martingales (see below) gives

$$\frac{u(X_0) + u(X_1) + u(X_2) + \dots + u(X_{n-1})}{n} \rightarrow 0 \quad (9)$$

almost surely. In terms of the function h this says that

$$\frac{h(X_0) + h(X_1) + u(X_2) + \dots + h(X_{n-1})}{n} \rightarrow \pi h \quad (10)$$

almost surely, where πh is the expectation computed with the invariant probability (the product of the probability row vector π with the column vector h). This is a strong law of large numbers for Markov chains. It is the idea underlying the Monte Carlo calculation of unknown invariant probabilities π .

General Results

Many classical results for sums of independent random variables have generalizations to the martingale setting. These include the strong law of large numbers and the central limit theorem.

The Kolmogorov form of the strong law of large numbers says the following. Let $Y_1, \dots, Y_n, \dots$ be a sequence of martingale difference random variables with finite variances $\sigma_1^2, \dots, \sigma_n^2, \dots$. Assume that the variances are uniformly bounded, or more generally that

$$\sum_{n=1}^{\infty} \frac{\sigma_n^2}{n^2} < \infty. \quad (11)$$

Then as $n \rightarrow \infty$ the sample means

$$\bar{Y}_n = \frac{Y_1 + \dots + Y_n}{n} \rightarrow 0 \quad (12)$$

almost surely (that is, with probability one). This is the law of averages in a very powerful and general form.

Fluctuations about the average are described by the central limit theorem. The setting for this theorem is a sequence $Y_1, \dots, Y_n, \dots$ of martingale difference random variables with finite variances $\sigma_1^2, \dots, \sigma_n^2, \dots$. Let

$$s_n^2 = \sigma_1^2 + \dots + \sigma_n^2 \quad (13)$$

be the variance of the sum $Y_1 + \dots + Y_n$.

The martingale differences satisfy the conditional variance normalization condition if

$$\frac{1}{s_n^2} \sum_{k=1}^n E[Y_k^2 | \mathcal{F}_{k-1}] \rightarrow 1 \quad (14)$$

in probability as $n \rightarrow \infty$.

Fix $\varepsilon > 0$. Consider one of the random variables Y_i . Say that it is large if $|Y_i| > \varepsilon s_n$. Define the large part of Y_i to be the random variable $Y_i^{\varepsilon s_n}$ that is equal to Y_i when Y_i is large and is equal to zero otherwise. The Lindeberg condition is that the contribution of the large values to the total variance is small, in the sense that for each $\varepsilon > 0$

$$\frac{1}{s_n^2} \sum_{i=1}^n E[(Y_i^{\varepsilon s_n})^2] \rightarrow 0 \quad (15)$$

as $n \rightarrow \infty$.

The central limit theorem states that if $Y_1, \dots, Y_n, \dots$ are martingale difference random variables with finite variances that satisfy the conditional variance normalization condition and the Lindeberg condition, then the distribution of

$$Z_n = \frac{Y_1 + \dots + Y_n}{s_n} \quad (16)$$

approaches the distribution of a standard normal random variable Z as $n \rightarrow \infty$. That is, the Gaussian distribution gives a universal description of fluctuations of martingales.

MATTER, NONLINEAR THEORY OF

A nonlinear theory of matter was first proposed in 1912 by Gustav Mie in a prescient series of papers that aimed to derive the elementary particles of matter as localized lumps of energy in a nonlinear field (Mie, 1912). To this end, Mie suggested a nonlinear augmentation of James Maxwell's electromagnetic equations out of which the electron would arise in a natural way.

Specifically, he defined a Lagrangian density ($\mathcal{L}$) depending upon electric field intensity ($\mathbf{E}$) and magnetic flux density ($\mathbf{B}$) and the four components of the electromagnetic potential ($\mathbf{A}, \phi$). Requiring dependence on the parameters $\eta \equiv (\mathbf{B}^2 - \mathbf{E}^2)$ and

$\chi \equiv (\phi^2 - \mathbf{A}^2)$ ensured relativistic invariance, and the specific choice $\mathcal{L} = \eta/2 + a\chi^3/6$ led to a static, spherically symmetric electric potential (ϕ) of the form

$$\phi(r) \approx \frac{(3r_0^2/a)^{1/4}}{\sqrt{r^2 + r_0^2}}. \quad (1)$$

Setting $4\pi(3r_0^2/a)^{1/4} = e$ (the electronic charge) yielded a spherically symmetric model for the electron with a radius of r_0 and electric potential

$$\phi(r) \rightarrow e/4\pi r$$

as $r \rightarrow \infty$. The Lorentz invariance that is built into the theory permits this solution to travel with any speed up to the limiting velocity of light with an appropriate Lorentz contraction.

Mie's approach to a nonlinear theory of matter was supported by Albert Einstein, who offered the following opinion in the mid-1930s (Einstein, 1954).

In the foundation of any consistent field theory, the particle concept must not appear in addition to the field concept. The whole theory must be based solely on partial differential equations and their singularity-free solutions.

Empirical support for this perspective was provided in the early 1930s by Carl Anderson's discovery of positron-electron creation from cosmic radiation. In other words, massive particles were observed to emerge from and collapse back into an electromagnetic field, which is not a property of the linear Maxwell equations.

Motivated by Anderson's observation, Max Born revisited Mie's nonlinear electromagnetics. Together with Leopold Infeld, he eliminated the χ -dependence in Mie's functional formulation and chose instead the Lagrangian density (Born & Infeld, 1934)

$$\mathcal{L} = E_0 \sqrt{1 + (\mathbf{B}^2 - \mathbf{E}^2)/E_0^2} - E_0^2, \quad (2)$$

where E_0 sets the field intensities at which nonlinearities arise. At low-field amplitudes, Equation (2) reduces to the classical Lagrangian density for Maxwell's equations: $\mathcal{L} = (\mathbf{B}^2 - \mathbf{E}^2)/2$. (Even with the currently available, high-intensity lasers, these vacuum nonlinearities would be difficult to observe, as E_0 is estimated to be about 10^{20} V/m in laboratory units.)

Among the solutions of this system, Born and Infeld found a spherically symmetric model electron with $\mathbf{E}$ finite everywhere, although the electric displacement ($\mathbf{D}$) exhibits a singularity at the origin. Erwin Schrödinger became interested in Born's theory as early as 1935 and continued working on it through the 1940s when—as founding director of the Dublin Institute for Advanced Studies—he attempted to move research in physics toward key areas of nonlinear science (Schrödinger, 1935).

Plane waves derived from Equation (2) obey the equation $(1 - u_t^2)u_{xx} + 2u_x u_t u_{xt} - (1 + u_x^2)u_{tt} = 0$,

where u is a component of the vector potential. Called the Born–Infeld equation, this system has been studied as an interesting nonlinear wave equation (Barbashov & Chernikov, 1966).

Einstein's conviction that a consistent theory for particle physics must be based on localized solutions of nonlinear partial differential equations was shared by several of his colleagues. In addition to Mie, Born, Infeld, and Schrödinger, Werner Heisenberg (1966), Louis de Broglie (1960, 1963), and David Bohm (1957) have suggested nonlinear field theories that in their simplest representations, can be viewed as the augmentation of linear field equations by a nonlinear term of the form $|u|^2 u$, as in the nonlinear Schrödinger equation. This nonlinearity conserves the integral

$$\int |u|^2 dr, \quad (3)$$

which can be interpreted as a mass.

The ideas of de Broglie and Bohm are related to those of the inverse scattering method (ISM). In their “theory of the double solution,” the real particle is a localized solution of a nonlinear equation with the form

$$u = Ue^{i\theta'}$$

Associated with this localized nonlinear solution is the solution of a corresponding linear equation

$$\psi = \Psi e^{i\theta}$$

with

$$\theta = \theta' \quad (4)$$

except in a small region surrounding the real particle. The function ψ is taken to be a solution of Schrödinger's quantum mechanical wave equation, and the phase condition of Equation (4) allows the particle to be guided by ψ . Similarly, in the context of the ISM, the nonlinear solution of a soliton equation is guided through space-time by the linear asymptotic solution of the associated linear operator. Although proposed almost a half century ago, the de Broglie–Bohm theory continues to offer possibilities for further studies (Holland, 1993).

During the 1960s, several investigators proposed the sine-Gordon (SG) equation as a field theory for elementary particles in one space dimension and time (Scott, 2003). This work gained momentum in the 1970s when it became known that special properties of the SG equation allow the corresponding quantum problem to be solved, showing that certain qualitative properties of the classical solution survive quantization (Dashen et al., 1974; Faddeev, 1975; Goldstone & Jakiw, 1975). In particular, the classical field energy was found to be a useful first approximation for the soliton mass, with quantum effects coming in as second-order corrections. More recently, this

approach has been developed into the concept of a skyrmion, which is a generalization of the SG kink, carrying its topological stability into three space dimensions.

These examples suggest that it may be possible to develop a nonlinear theory of matter by proceeding as follows. First, guess a classical version of the correct nonlinear field. Second, solve this classical system for salient aspects of localized behavior. Third, analyze the corresponding quantum theory to obtain exact values for the mass spectrum. Finally, compare calculated values of mass with measured mass spectra. As Einstein was aware, however, this is a daunting program because there are no theoretical bounds on the range of conceivable nonlinear theories; thus, it is not surprising to find a proliferation of partially evaluated theories. In addition to the Born–Infeld, de Broglie, and skyrmion formulations, present candidates include string theory and the Yang–Mills equation. What others are out there?

MAXWELL-BLOCH EQUATIONS

The Maxwell-Bloch (MB) equations arise in nonlinear optics, where they couple “two-level atoms” to Maxwell’s electromagnetic field equations to model a nonlinear dielectric. Although the two-level atom is a pseudo-atom with only two nondegenerate energy levels, it can be realized in practice by real atoms excited by light close to a suitable atomic resonance, and it can be modeled as a two-state system: $|g\rangle$ (for ground) and $|e\rangle$ (for excited). Transitions between the two states are allowed, and there is a quantum mechanical matrix element $p = q\langle g|r|e\rangle \neq 0$ between them in dipole approximation, where q is the electronic charge and qr is the dipole transition operator.

The outer products of $|e\rangle$ and $|g\rangle$ form a Lie algebra with

$$S^z = \frac{1}{2}(|e\rangle\langle e| - |g\rangle\langle g|),$$

$$S^+ = |e\rangle\langle g|,$$

$$S^- = |g\rangle\langle e|.$$

By choosing $\langle e|e\rangle = \langle g|g\rangle = 1$, $\langle e|g\rangle = \langle g|e\rangle = 0$ (orthonormality), one finds that the Lie algebra is

$$[S^z, S^+] = S^+, \quad [S^z, S^-] = -S^-,$$

$$[S^+, S^-] = 2S^z,$$

where $[,]$ is the Lie bracket or “commutator” (Bullough et al., 1995b). Constructed from $|e\rangle$ and $|g\rangle$, this is a two-dimensional representation of $\text{su}(2)$, corresponding to a spin- $\frac{1}{2}$ system in which $|e\rangle$ is spin-up and $|g\rangle$ is spin-down. In a magnetic field $\mathbf{B} = (B_x, B_y, B_z)$, a magnetic dipole μ has a Hamiltonian which can be taken in the form of a 2×2 Hamiltonian matrix with elements (Feynman et al., 1966, pp. 10–14)

$$H_{11} = -\mu B_z, \quad H_{12} = -\mu(B_x - iB_y),$$

$$H_{21} = -\mu(B_x + iB_y), \quad H_{22} = +\mu B_z.$$

There is an exact correspondence for the dipole p of the two-level atom in an electric field $\mathbf{E}$, and the two-level atom is a pseudo-spin- $\frac{1}{2}$ system (Bullough et al., 1995b). As any state $|\psi(t)\rangle$ at time t in the two-dimensional Hilbert space can be written $|\psi(t)\rangle = c_1(t)|e\rangle + c_2(t)|g\rangle$, the correspondence extends to the dynamics. From the Hamiltonian H_{ij} , Schrödinger’s equation for the amplitudes $c_i(t)$ ($i = 1, 2$) becomes

$$i\hbar\dot{c}_1 = -\mu[B_z c_1 + (B_x - iB_y)c_2],$$

$$i\hbar\dot{c}_2 = -\mu[(B_x + iB_y)c_1 - B_z c_2].$$

When $B_x = B_y = 0$, $B_z = \text{constant}$ independent of t , $c_1(t)$, $c_2(t)$ evolve as $c(t)e^{\pm i\omega_0 t}$, and $\omega_0 = 2\mu B_z \hbar^{-1}$ is a Larmor frequency for the spinning (precessing) magnet of moment μ . The free two-level atom with resonance frequency ω_0 thus acts as a true spin- $\frac{1}{2}$ in a fixed magnetic field B_z .

If we construct the Bloch vector $\mathbf{r}(t) = (r_1(t), r_2(t), r_3(t))$

$$r_1 = (c_1 c_2^* + c_1^* c_2), \quad r_2 = -i(c_1 c_2^* - c_1^* c_2),$$

$$r_3 = (|c_1|^2 - |c_2|^2)$$

(c_i^* = complex conjugate of c_i), the equations of motion for $c_1(t)$, $c_2(t)$ become the Bloch equation

$$\dot{\mathbf{r}} \equiv d\mathbf{r}/dt = \omega \times \mathbf{r} \quad (1)$$

for a spin- $\frac{1}{2}$ particle, where $\omega \equiv (-2\mu B_x \hbar^{-1}, -2\mu B_y \hbar^{-1}, -2\mu B_z \hbar^{-1})$. (For the two-level atom in a real electric field $E(t)$, $\omega \equiv (-2pE\hbar^{-1}, 0, \omega_0)$.) The normalization $|c_1|^2 + |c_2|^2 = 1$ means $|\mathbf{r}|^2 = 1$, and the motion is confined to the surface of a sphere (the Bloch sphere) of unit radius: spin-up = $(0, 0, 1)$, spin down = $(0, 0, -1)$ on this sphere. This description omits a Berry’s phase.

Two-level atoms enter laser physics via the Jaynes-Cummings (JC) model, which couples one two-level atom to a single mode of the quantized electromagnetic field of frequency ω . The Hamiltonian is

$$H = \omega_0 S^z + \omega a^\dagger a + g(a^\dagger S^- + S^+ a),$$

where g is a (real and positive) coupling constant, S^z , $S^\pm$ satisfy the $\text{su}(2)$ algebra given above, and a , $a^\dagger$ satisfy $[a, a^\dagger] = 1$ and the Heisenberg-Weyl algebra of standard bosons.

The number operator $N = S^z + a^\dagger a + 1/2$ commutes with H . The JC model is thus quantum integrable, there being two degrees of freedom (spin and the quantum oscillator), and there are exactly two commuting constants H and N . The model can be solved exactly in terms of 2×2 matrices (Bullough et al., 1995a) and also by the quantum inverse method in Bogoliubov et al. (1996). By coupling the JC model to a heat-bath, one obtains the master equation for a micromaser. (Such a nonlinear quantum device is in operation at the Max Planck Institute, Garching, Germany, using ^{85}Rb atoms which enter a cavity in their upper states $|e\rangle$ but may leave it in $|e\rangle$ or $|g\rangle$.)

The JC model evolves only in time and is a fundamental nonlinear quantum model. One obtains important nonlinear quantum field theories by coupling two-level atoms to Maxwell’s electromagnetic field equations

$$\nabla^2 \hat{\mathbf{E}} - c^{-2} \partial^2 \hat{\mathbf{E}} / \partial t^2 = 4\pi n c^{-2} \partial^2 \hat{\mathbf{P}} / \partial t^2. \quad (2)$$

Here, c is the speed of light in a vacuum, n is the number of two-level atoms per unit volume, and $\hat{\mathbf{E}} = \hat{\mathbf{E}}(\mathbf{x}, t)$ and $n\hat{\mathbf{P}} = n\hat{\mathbf{P}}(\mathbf{x}, t)$ are, respectively, the electric field and dipole density operators. This operator Maxwell equation and the operator Bloch equation for the dipole density constitute the quantum operator form of the MB equations.

If the electric fields are strong enough (many photons), both $\vec{E}$ and $\vec{P}$ can be regarded as classical variables, while quantum mechanics still enters through the atoms. The classical electric field $\mathbf{E}(\mathbf{x}, t)$ acts on the atom at $\mathbf{x}$ at time t through vectors $\omega(\mathbf{x}, t)$ given at points $\mathbf{x}$ and time t through

$$\omega(\mathbf{x}, t) \equiv (-2\mathbf{p} \cdot \mathbf{E}(\mathbf{x}, t)\hbar^{-1}, 0, \omega_0)$$

and the Rabi frequency is $|2\mathbf{p} \cdot \mathbf{E}(\mathbf{x}, t)|\hbar^{-1}$. This form of $\omega(\mathbf{x}, t)$ shows the coupling between the Maxwell equations and the Bloch equations to form the semi-classical MB equations, and the coupling is nonlinear since $\mathbf{E}(\mathbf{x}, t)$ is driven by $\mathbf{p}r_1(\mathbf{x}, t)$ for $\mathbf{P}(\mathbf{x}, t)$ in the (linear) Maxwell equation.

In one space dimension (x) one obtains the standard form of the semiclassical MB equations (Eilbeck et al., 1973). The (linear) Maxwell equations for such an $E(x, t)$ and $P(x, t) = pr_1(x, t)$ is

$$\partial^2 E / \partial x^2 - (1/c^2) \partial^2 E / \partial t^2 = (4\pi np/c^2) \partial^2 r_1 / \partial t^2. \quad (3)$$

With $\omega(x, t) \equiv (-2pE(x, t)\hbar^{-1}, 0, \omega_0)$, the Bloch equation (1) can be written out explicitly as

$$\begin{aligned} \partial r_1 / \partial t &= -\omega_0 r_2, \\ \partial r_2 / \partial t &= \omega_0 r_1 + 2p\hbar^{-1} E r_3, \\ \partial r_3 / \partial t &= -2p\hbar^{-1} E r_2. \end{aligned} \quad (4)$$

This system of four nonlinear partial differential equations (3) with (4) is not integrable, but it becomes an integrable field theory if the Maxwell equation is replaced by the unidirectional system (valid for small densities in the one space dimension)

$$\partial E / \partial x + (1/c) \partial E / \partial t = (-2\pi np/c) \partial r_1 / \partial t. \quad (5)$$

Equations (4) and (5) comprise the reduced Maxwell–Bloch (RMB) equations, which can be explicitly integrated by the AKNS inverse scattering method as in Gibbon et al. (1973).

Under a slowly varying envelope and phase approximation (SVEPA), the envelope equations become the self-induced transparency (SIT) equations

$$\begin{aligned} \partial \mathcal{E} / \partial x + (1/c) \partial \mathcal{E} / \partial t &= \alpha P, \\ \partial P / \partial t &= \mathcal{E} N + \Delta \omega' Q, \\ \partial N / \partial t &= -\mathcal{E} P, \\ \partial Q / \partial t &= -\Delta \omega' P. \end{aligned} \quad (6)$$

In these SIT equations, $\Delta \omega' \equiv \omega'_0 - \omega_0$ (called inhomogeneous broadening), and ω'_0 is a shifted resonance frequency for any particular atom (induced by Doppler shifts, e.g.) while P , Q , N depend on $(x, t, \Delta \omega')$ and N replaces the inversion r_3 of the atom in the Bloch vector. It is an unfortunate confusion of the literature that what we call the SIT equations are also called the Maxwell–Bloch equations. Here, we reserve MB for the

Maxwell equation coupled to the three Bloch equations which are *not* envelope equations.

The SIT equations (6) must be averaged over inhomogeneous broadening $\Delta \omega'$ but remain integrable. The soliton solution is the 2π -pulse of (McCall & Hahn, 1969) and there are multi-soliton solutions. Under a sharp line resonance condition, they further reduce to the standard form of the sine-Gordon (SG) equation

$$\partial^2 \phi / \partial x^2 - \partial^2 \phi / \partial t^2 = \sin \phi. \quad (7)$$

Under an SVEPA, the SG equation becomes the attractive case of the nonlinear Schrödinger (NLS) equation. The RMB, SIT, SG, and attractive NLS equations form a hierarchy of integrable nonlinear field theories in which integrability is handed down by the SVEPA in the fashion described by Calogero in 1995 (see Bullough, 2001).

The two-dimensional representations of $su(2)$ for two-level atoms extend to three-dimensional representations of $su(3)$ for three-level atoms, and the consequent appropriately generalized SIT equations are fundamental to electromagnetically induced transparency (EIT) and the storage of quantum information (Bullough, 2001; Hau, 2001; Haroche & Raimond, 1993; Bullough & Gibbs, 2004).

MCCULLOCH-PITTS NETWORK

In 1943, Warren McCulloch and Walter Pitts published a seminal paper that described the first attempt to provide a mathematical model of a neuron (McCulloch and Pitts, 1943). This work explored the properties of networks of such mathematical neurons in relation to the working of the nervous system. The model arose from the following assumptions based on the knowledge of neurophysiology at the time

- (i) The activity of the neuron is an “all-or-none” process.
- (ii) A certain fixed number of synapses must be excited within the period of latent addition in order to excite a neuron at any time, and this number is independent of previous activity and position on the neuron.
- (iii) The only significant delay within the nervous system is synaptic delay.
- (iv) The activity of any inhibitory synapse absolutely prevents excitation of the neuron at that time.
- (v) The structure of the net does not change with time.

The McCulloch–Pitts neuron is thus a binary threshold unit whose firing or activation is dependent on the values of its inputs. The neuron receives a number of excitatory (positive) or inhibitory (negative) inputs via “synaptic” connections. Excitatory synapses are equally weighted, and if the sum of these positive input signals exceeds some value, θ , the neuron fires. Otherwise, the neuron does not fire. If a signal is received on any of the negative inputs, the neuron cannot fire, regardless of the positive input values. The threshold value θ is a fixed threshold value unique to the neuron, and the model is assumed to be operating in discrete time steps.

A network of McCulloch–Pitts neurons can be assembled by connecting the outputs of neurons to the inputs of other neurons in some manner. In dis-

cussing networks of these artificial neurons, McCulloch and Pitts distinguish between nets with and without “circles.” In a network without circles, it is not possible to follow a path of connections in the network from any given neuron and return to that same neuron. In other words, there are no closed causal loops. The activity in such a network will, therefore, have a feed-forward dynamic; any activity imposed on the network will propagate in a unidirectional fashion for a finite amount of time, terminating when neurons are encountered with no outgoing synaptic connections. The perceptron (Rosenblatt, 1962) and multi-layer perceptron (see e.g., Haykin, 1999) networks are examples of this kind of topology. A McCulloch–Pitts network without circles is capable of representing any statement within prepositional logic (i.e., any finite logical expression).

The dynamics of networks with circles are more complex. Activity in these networks may propagate indefinitely around the network in discrete time, so the firing activity of the network at any time may be dependent on the activity of the network at multiple stages in the past.

McCulloch and Pitts were able to show that such nets are equivalent to a Universal Turing Machine in principle. It should, however, be noted that the proofs for McCulloch–Pitts nets are existence proofs only in the sense that they do not imply an algorithm for constructing a network, with appropriate values of threshold and weight parameters, to compute a given function. Also, they do not consider computational time. Interestingly, the work of McCulloch and Pitts was also an influence in the development of the von Neumann stored program computer architecture.

Consider a McCulloch–Pitts net with circles. At any point in time, the state of the network can be defined by the current (binary) activity pattern of the neurons (i.e., which neurons are firing and which are not). The network can be thought of as a point in a configuration space of all possible activity patterns. Under some appropriately chosen scheme for updating the state of the network (synchronously or asynchronously), the activity may converge to an attractor in the configuration space, resulting in a stable state for subsequent time steps. This is the basis for attractor neural nets, as described by Hopfield in the context of simple associative memory networks (Hopfield, 1982).

MEAN FIELD THEORIES

See **Phase transitions**

MEASURES

Measures provide the means to introduce probabilistic methods into the study of a dynamical system by supplying a notion of the size or content of sets that is additive—the measure of a union of disjoint sets is the sum of the measures of these sets.

Sets correspond to events and the measure of a set to the probability of that event. The precursor to this general notion is that of the phase volume in a classical mechanical system, which is preserved under the phase flow (Liouville theorem). In other words, if a set of initial conditions is transported by the flow for a fixed time then the set of terminal conditions has the same volume as the set of initial conditions. Put differently, the phase flow consists of volume-preserving maps. In the general context of measures, this corresponds to measure-preserving transformations (see below), which are the subject of ergodic theory. For example, the Birkhoff ergodic theorem establishes a connection between the measure of a set and the proportion of time a typical orbit spends in it. The original result in ergodic theory is the Recurrence Theorem by Poincaré (1890) according to which almost every point in a volume-preserving system has to return arbitrarily close to its initial position.

The *Lebesgue measure* coincides with volume, but it is defined on a larger collection of sets. For example, the one-dimensional volume (length) of the set of rational numbers is not defined, but this set has zero Lebesgue measure. Closely related to the Lebesgue measure are *absolutely continuous* measures, that is, those defined by integrating a nonnegative density function over the set to be measured. The function can be interpreted as a probability density if the total integral is 1. (The bell curve $p(x) := e^{-(x-b)^2/2a^2}/a\sqrt{2\pi}$ is a standard example.) Taking the Dirac δ -function as a (singular) “density,” one obtains the *Dirac measure* defined by $\delta_p(U) = 1$ if $p \in U$, $\delta_p(U) = 0$ otherwise.

In general, a measure is a nonnegative additive set function. More precisely, it is a nonnegative function (with $+\infty$ an allowed value) defined on a collection of subsets (which are then said to be measurable) of the space in question, such that the union of any countable

or finite union of disjoint measurable sets A_i is measurable (this is a requirement of the collection of measurable sets), and its measure is the sum of the measures of the A_i . (One cannot require an analogous property for unions of uncountably many sets because the real line is a disjoint union of points, each of which has zero Lebesgue measure.) One often is interested in finite measures, that is, those for which the measure of the whole space is finite. These can be rescaled to a *probability measure* (the whole space has measure 1). A set of measure zero is referred to as a *null set*, and a property is said to hold *almost everywhere* if it fails for only a null set of points.

If every open set is measurable and every compact set has finite measure, then the measure is said to be a *Borel measure*. This is a useful notion because a Borel measure μ is regular; that is

$$\begin{aligned}\mu(A) &= \inf\{\mu(O) : A \subset O \text{ and } O \text{ is open}\} \\ &= \sup\{\mu(B) : B \subset A \text{ and } B \text{ is compact}\}.\end{aligned}$$

Up to a scale factor, one defines the Lebesgue measure $\mu_n(A)$ of a set $A \subset \mathbb{R}^n$ by considering collections of balls whose union contains A and minimizing the sums of the volumes of these balls:

$$\mu_n(A) = \inf \left\{ \sum_i r_i^n : A \subset \bigcup_i B(x_i, r_i) \right\}.$$

Replacing the exponent n of the radii by an arbitrary exponent α that is not necessarily related to the dimension of the ambient space, one obtains the α -dimensional *Hausdorff measure* μ_α . For example, for a smooth curve c of length $l(c)$ in the plane, we get $\mu_1(c) = l(c)$ and $\mu_2(c) = 0$. Indeed, one can characterize the *Hausdorff dimension* of a set S via Hausdorff measures. It is the number α_0 such that $\mu_\alpha(S) = +\infty$ for $\alpha < \alpha_0$ and $\mu_\alpha(S) = 0$ for $\alpha > \alpha_0$.

A measure is *invariant* under a map f and the map is said to be *measure-preserving*, if for any measurable set A the set $f^{-1}(A) := \{x : f(x) \in A\}$ is measurable and has the same measure as A . This preimage definition turns out to be the proper one for noninvertible maps. For example, circle rotations $z \mapsto ze^{2\pi i \theta}$ preserve the Lebesgue measure because they preserve length. The doubling map $z \mapsto z^2$ of the unit circle in the complex plane preserves the Lebesgue measure because the preimage of an arc consists of two arcs of half the length. The density $1/(1+x)$ on $[0, 1]$ defines a measure μ , which is invariant under the Gauss map $G: [0, 1] \rightarrow [0, 1]$ defined by $x \mapsto \{1/x\}$ (fractional part): $a = \{1/x\}$ if and only if $1/x = a + n$ for some $n \in \mathbb{N}$, so

$$\begin{aligned}\mu(G^{-1}([a, b])) &= \sum_{n \in \mathbb{N}} \int_{1/b+n}^{1/a+n} \frac{1}{1+x} dx \\ &= \sum_{n \in \mathbb{N}} \log \left(1 + \frac{1}{a+n} \right)\end{aligned}$$

$$\begin{aligned} & -\log\left(1+\frac{1}{b+n}\right) \\ & =\sum_{n \in \mathbb{N}} \log (a+n+1)-\log (a+n) \\ & \quad -\log (b+n+1)+\log (b+n) \\ & =\log (b+1)-\log (a+1) \\ & =\int_a^b \frac{1}{1+x} \mathrm{d} x=\mu([a, b]) . \end{aligned}$$

The Dirac measure δ_p concentrated on a fixed point p is always invariant.

The *Birkhoff ergodic theorem* guarantees the existence of time averages of orbits. If φ is an observable (a continuous or merely measurable scalar function on phase space) and μ is an f -invariant measure, then for almost every point the time (or Birkhoff or ergodic) average

$$\lim _{n \rightarrow \infty} \sum_{i=0}^{n-1} \varphi\left(f^i(x)\right) / n$$

exists. A map f is said to be *ergodic* if the phase space is indecomposable in the following sense. If A is an invariant set (i.e., $f^{-1}(A)=A$), then either A or its complement is a null set. This is the case for the Lebesgue measure and the doubling map or rotations by an irrational angle, but not for rotations by a rational angle. For ergodic systems, the time average over almost every orbit equals the space average $\int \varphi \mathrm{d} \mu$.

A particularly interesting measure with respect to the study of hyperbolic attractors and strange attractors is the *Sinai–Ruelle–Bowen measure*. By definition it has a positive Lyapunov exponent almost everywhere and absolutely continuous conditionals (marginals) on unstable manifolds. If such a measure is ergodic and has no zero Lyapunov exponents, then it gives a natural or physical (physically observed) measure, which is defined by the following property. While for any invariant measure μ the Birkhoff ergodic theorem implies that almost every point is μ -equidistributed, the physical measure reflects the asymptotic distribution of Lebesgue-almost every point (or at least that of a set of points of positive Lebesgue measure). This means that if one picks a point at random (with respect to Lebesgue measure), its orbit will be equidistributed uniformly with respect to the physical measure. In other words, a physical (or natural) measure represents the density of points obtained from a computed orbit. For example, the Dirac measure concentrated on an attracting fixed point is a natural measure.

MECHANICS OF SOLIDS

Two aspects may be discerned in the historical development of the mechanics of solids. The first of these was motivated by technical requirements, and the second was motivated by studies in theoretical physics. Sometimes these two aspects interacted, but each of them has maintained its specificity.

From the fundamental continuum hypothesis, the mechanics of solids admits an introduction of vector and tensor fields describing the strained state of a solid as a result of its deformation: the displacement vector and tensors of stress and strain. Physical features are manifested by the constitutive relations (algebraic, differential, or integro-differential), which determine the coupling between stress and strain tensors, and Newton’s equations of motion can be constructed taking into account all relations mentioned above.

There are two sources of nonlinearity in the mechanics of solids. If the constitutive relations are nonlinear, one deals with an intrinsically nonlinear problem. Nonlinearity also arises from purely geometric reasons (nonlinear dependence of the strains on displacements) and is called geometric nonlinearity. Four important approximations illustrating the basic nonlinear effects in the mechanics of solids are as follows.

<i>Prerequisites of approximations:</i>	<i>Result of approximation:</i>
(a) Rotational and translational invariance of infinite undeformed solid	Infinite isotropic media
(b) Discrete group of symmetry	Anisotropic crystal
(c) Details of microstructure	Media with weak or strong dispersion
(d) Smallness of one or two dimensions	Bar, plate, shell

Taking account of the shear, nonlinear dynamic equations for an infinite elastic body can be considered as an extension of the hydrodynamics of a compressible non-viscous fluid. Lagrange’s equations of motion in

the main nonlinear approximation are written as follows (Blend, 1969):

$$\rho \frac{\partial^2 u_j}{\partial t^2} - \frac{\partial}{\partial u_j} \left(\frac{\partial U}{\partial u_{i,j}} \right) = X_{i,j},$$

$$U = \frac{1}{2} \lambda I_1^2 + \mu I_2 + T_0 S - \kappa I_1 S + \text{higher-order terms},$$

$$i, j = 1, 2, 3, \quad (1)$$

where ρ_0 is the initial density of the elastic media, $X_{i,j}$ are components of external loading, u_j are components of the displacement vector, U is a potential, $I_1 = \varepsilon_{ij}$ and $I_2 = \varepsilon_{ij} \varepsilon_{ij}$ are the first and second invariants of the strain tensor, λ and μ are Lamé coefficients characterizing the elastic properties of isotropic media, S is entropy, κ is the coefficient of heat conductivity, and T_0 is the initial temperature. Lamé coefficients can be expressed via the Young's modulus E and Poisson coefficient ν , describing longitudinal elastic resistance and transversal deformation, respectively, for a specimen subjected to uniaxial longitudinal loading.

In this case, geometric nonlinearity is caused by nonlinear dependence of ε_{ij} on derivatives of displacements, and physical nonlinearity is accounted for by high-order terms involving strains ε_{ij} . A significant consequence of nonlinearity may be the possibility of shock waves manifested by discontinuity of the first or second derivatives of displacements (strong or weak discontinuities), respectively.

The simplest and most important problem admitting discontinuous solutions in nonlinear theory is the description of plane adiabatic shock waves propagation. In this case, nonlinear partial differential equations (1) are replaced by nonlinear algebraic relations. These relations are determined by conservation laws for mechanical and thermodynamical quantities as well as by the second law of thermodynamics. The main difference from shock waves in the fluid is manifested in the presence of shear shock waves.

Taking into account microstructure and intermolecular (physical) nonlinearity in the constitutive relations, one obtains in the lowest approximation for plane waves the Korteweg–de Vries (KDV) equation (Askar, 1985)

$$\frac{\partial w}{\partial \tau} + \frac{1}{2} \alpha_1 w \frac{\partial w}{\partial \zeta} + \frac{1}{24} \frac{\partial^3 w}{\partial \zeta^3} = 0,$$

where τ and ζ are dimensionless time and space coordinates, respectively, and $w(\tau, \zeta)$ is a dimensionless deformation of the media. Due to the presence of nonlinear (second) and dispersion (third) terms, this equation has a stable soliton solution (compression wave) as well as multiple soliton solutions.

A second new aspect, important for media with microstructure, is the possibility of a short wavelength continuum approximation. Such an approximation is valid for the envelopes of short waves for which the

wavelengths are comparable with the characteristic length of microstructure (Manevitch, 2001). In this case, equations of motion for the plane waves can be reduced to the dimensionless nonlinear Schrödinger (NLS) equation

$$\frac{\partial \varphi_0}{\partial \tau} - i \alpha |\varphi_0|^2 \varphi_0 - i \frac{\partial^2 \varphi_0}{\partial \zeta^2} = 0,$$

where $\varphi_0 = [\exp i \tau](w - i u)$, u is the displacement, w is the velocity, α is a nonlinear parameter, and τ and ζ are dimensionless time and space coordinates. An important manifestation of nonlinearity in this case is the existence of envelope solitons

$$\varphi_0(\zeta, \tau) = \sqrt{2S/\alpha e} e^{i(k\zeta - \omega\tau)} \operatorname{sech}[\sqrt{S}(\zeta - \nu\tau)],$$

where $k = \nu/2$ and $\omega = \nu^2/4 - S$.

Dispersion effects can be also caused by the presence of boundaries as in the case of a rod embedded in another elastic external medium. Along with physical and/or geometric nonlinearity, this may lead to formation of solitons similar to solitons in media with microstructure (Samsonov et al., 1999).

Note that the formation of shock waves in three-dimensional elastic media requires much more energy than in the common case of sound waves. Contrary to this, geometric nonlinearity in thin elastic bodies described by simplified one- and two-dimensional models provides easy manifestation of nonlinear effects due to bifurcation of equilibrium states (elastic instability). Elastic instability may lead to localization of buckling and coupling of linear modes—a sign of strong nonlinearity (Thomson & Hupt, 1973). Thin-walled structures also demonstrate numerous other effects typical of common nonlinear systems, including period doubling and internal resonance, transition to spatial, and temporal chaos. Future developments in nonlinear mechanics of solids will focus on the study of these effects as well as the propagation of nonlinear waves in anisotropic and nonhomogeneous media and on mechanics of solids at the mesoscopic level (Alexander, 1998).

MEL'NIKOV METHOD

In 1963, V.K. Mel'nikov developed an analytical method for the study of time-periodic perturbations of a planar autonomous system. This method permits determination of persistence and stability of subharmonic motions and measurement of infinitesimal separation of stable and unstable manifolds of hyperbolic fixed points. The Mel'nikov method is one of the few analytical tools for establishing conditions for homoclinic chaos, and it has been generalized to many settings, including Hamiltonian systems with higher degrees of freedom and partial differential equations.

The main ideas can be introduced in the context of a periodically forced planar Hamiltonian system:

$$\begin{aligned}\dot{x} &= \frac{\partial H}{\partial y} + \varepsilon f_1(x, y, t), \\ \dot{y} &= -\frac{\partial H}{\partial x} + \varepsilon f_2(x, y, t).\end{aligned}$$

$H(x, y)$ is the Hamiltonian function of the unperturbed system ($\varepsilon = 0$), and $\mathbf{f} = (f_1, f_2)^T$ is a time-periodic perturbation vector field. Both H and $\mathbf{f}$ are assumed to be sufficiently smooth functions of their arguments.

Assume that the unperturbed system possesses a homoclinic orbit $q_h(t)$ to a hyperbolic saddle point p_0 , as shown in Figure 1. When $\varepsilon \neq 0$, a perturbation argument guarantees persistence of a hyperbolic fixed point p_ε , and local existence of its stable and unstable manifolds, parametrized, respectively, by solutions $q_\varepsilon^s(t) = q_h(t - t_0) + \varepsilon q_1^s(t) + \mathcal{O}(\varepsilon^2)$ and $q_\varepsilon^u(t) = q_h(t - t_0) + \varepsilon q_1^u(t) + \mathcal{O}(\varepsilon^2)$.

As the unperturbed separatrix is expected to split under perturbation, it is convenient to introduce the distance function

$$\begin{aligned}d(t_0) &= (\partial_x H, \partial_y H)^T|_{q_h(0)} \cdot [q_\varepsilon^u(t_0) - q_\varepsilon^s(t_0)] \\ &= \varepsilon [(\partial_x H, \partial_y H)^T|_{q_h(0)} \wedge (q_1^u(t_0) - q_1^s(t_0))] \\ &\quad + \mathcal{O}(\varepsilon^2),\end{aligned}$$

which measures the displacement of the stable and unstable manifolds of p_ε along a direction normal to the unperturbed separatrix (represented by vector $\mathbf{N}$ in Figure 1). After deriving an evolution equation for the perturbation expansion of the distance function $d(t)$, we arrive at the following expression:

$$d(t_0) = \varepsilon M(t_0) + \mathcal{O}(\varepsilon^2). \quad (1)$$

The Mel'nikov function $M(t_0)$ is defined by

$$M(t_0) = \int_{-\infty}^{+\infty} \mathbf{grad} H(q_h(t - t_0)) \cdot \mathbf{f}(q_h(t - t_0), t) dt, \quad (2)$$

Figure 1. Unperturbed and perturbed separatrices.

where the integrand is the scalar product of vectorfields $\mathbf{grad} H$ and $\mathbf{f}$ and is evaluated along the unperturbed homoclinic orbit.

As an example, consider the following planar system of ordinary differential equations with periodic perturbation:

$$\begin{aligned}\dot{x} &= y, \\ \dot{y} &= -x + x^2 + \varepsilon \sin t.\end{aligned}$$

The unperturbed system has Hamiltonian $H(x, y) = y^2/2 + x^2/2 - x^3/3$ and two fixed points: the origin (a center) and the point of coordinates $(1, 0)$ (a saddle point). The unperturbed homoclinic orbit (parametrizing the degenerate stable, unstable manifolds of the hyperbolic fixed point) is given by

$$\begin{aligned}q_h(t - t_0) &= \left(\frac{3}{2} \tanh^2 \left(\frac{t - t_0}{2} \right) - \frac{1}{2}, \right. \\ &\quad \left. \frac{3}{2} \tanh \left(\frac{t - t_0}{2} \right) \sinh^2 \left(\frac{t - t_0}{2} \right) \right)^T, \quad (3)\end{aligned}$$

and the corresponding Mel'nikov function is computed to be

$$\begin{aligned}M(t_0) &= \frac{3}{2} \int_{-\infty}^{+\infty} \tanh(t/2) \sinh^2(t/2) \sin(t + t_0) dt \\ &= -\frac{3\pi \cos(t_0)}{2 \sinh \pi/2 \cosh \pi/2}.\end{aligned} \quad (4)$$

If, as in this example, $M(t_0)$ has an infinite sequence of nondegenerate zeros, an infinite number of transverse homoclinic orbits of the hyperbolic fixed point of the perturbed system is guaranteed to exist for all $\varepsilon \neq 0$ sufficiently small. Thus, the system exhibits homoclinic chaos.

For perturbations containing dissipative or constant forcing terms, the Mel'nikov integral may be nonvanishing. In such cases, the separatrix still splits under perturbation, but no transverse homoclinic points occur.

Generalizations of the Mel'nikov method to higher-dimensional systems have been discussed by various authors (see, for example, Yagasaki (1999), Gruendler (1992), and the monograph by Wiggins (1988, pp. 1–16)).

Autonomous Perturbations in Two Degrees of Freedom

Consider how this method applies to autonomous near-integrable Hamiltonian systems with two degrees of freedom. This case was first treated, and then generalized to integrable equations with $n + 1$ degrees of freedom, by Holmes and Marsden (1982a,b). These authors assume that the unperturbed Hamiltonian has the form $H_0 = F(x, y) + G(I)$, where F is the Hamiltonian of a planar system with a homoclinic orbit to a hyperbolic fixed point, and G is the Hamiltonian of a planar system in action-angle coordinates. By restricting to the energy surface, the original equations are reduced to a single-degree-of-freedom non-autonomous system, to which the usual Mel'nikov technique is applied.

A more direct approach by Robinson (1996) assumes Hamiltonians of the general form

$$H_\varepsilon(\mathbf{x}) = H_0(\mathbf{x}) + \varepsilon H_1(\mathbf{x}), \quad \mathbf{x} \in \mathbb{R}^4. \quad (5)$$

The unperturbed system is assumed to be completely integrable, with a second constant of motion K , and to possess a hyperbolic periodic orbit γ_0 . The stable and unstable manifolds of γ_0 , $\mathcal{W}^s(\gamma_0) = \mathcal{W}^u(\gamma_0)$, are parametrized by a two-dimensional family of homoclinic orbits $q_h(t, \mathbf{x}_0)$, where $\mathbf{x}_0$ is a point on the corresponding level set $H_0(\gamma_0) = h_0$.

Because the perturbation is Hamiltonian, the perturbed hyperbolic periodic orbit γ_ε and its stable, unstable manifolds $\mathcal{W}^{s,u}(\gamma_\varepsilon)$ continue to lie within the same energy surface $H_\varepsilon^{-1}(h_0)$. Thus $\mathbf{grad} H_0$ no longer provides a good measurement of their transversal splitting.

Letting Π_0 be a two-dimensional plane transversal to the unperturbed separatrix at $\mathbf{x}_0$ and denoting by $\zeta^{s,u}(\mathbf{x}_0, h_0; \varepsilon) = \Pi_0 \cap \mathcal{W}^{s,u}(\gamma_\varepsilon)$ the corresponding points on the perturbed invariant manifolds, one computes the infinitesimal displacement in terms of the second integral K :

$$M(\mathbf{x}_0, h_0) = \frac{\partial}{\partial \varepsilon} [K \circ \zeta^u(\mathbf{x}_0, h_0; \varepsilon) - K \circ \zeta^s(\mathbf{x}_0, h_0; \varepsilon)]|_{\varepsilon=0}. \quad (6)$$

The Mel'nikov measurement can be reduced (Robinson, 1996) to the following conditionally convergent integral:

$$M(\mathbf{x}_0, h_0) = \lim_{j \rightarrow \infty} \int_{-T_j^*}^{T_j} \mathbf{grad} F \cdot \mathcal{J} \mathbf{grad} H_1|_{q_h(t, \mathbf{x}_0)} dt, \quad (7)$$

where $\mathcal{J} \mathbf{grad} H_1$ is the Hamiltonian vector field of the perturbation, and $-T_j^*$, T_j are chosen so that $q_h(-T_j^*, \mathbf{x}_0)$ and $q_h(T_j, \mathbf{x}_0)$ converge to the same point of the periodic orbit γ_0 .

An Elastic Pendulum

Consider the application of these ideas to the following four-dimensional dynamical system modelling an elastic pendulum (Holmes and Marsden, 1982a):

$$\begin{aligned} \dot{x} &= y, \\ \dot{y} &= \sin x + \varepsilon \left(\sqrt{\frac{2I}{\omega}} \sin \theta - x \right), \\ \dot{I} &= \varepsilon \sqrt{\frac{2I}{\omega}} \left(\sqrt{\frac{2I}{\omega}} \sin \theta - x \right) \cos \theta, \\ \dot{\theta} &= \omega - \varepsilon \frac{1}{\sqrt{2I\omega}} \left(\sqrt{\frac{2I}{\omega}} \sin \theta - x \right) \sin \theta. \end{aligned}$$

The unperturbed equations are completely integrable with constants of motion $H_0(x, y, I, \theta) = \frac{1}{2}y^2 - \cos x + \omega I$ and $K(x, y, I, \theta) = I$. The energy surface $H_0(\mathbf{x}) = 1 + \omega I = h_0$ contains a hyperbolic periodic orbit $\gamma_0 = (\pi, 0, I, \omega t)^T$ and its two-dimensional stable and unstable manifolds, parametrized by the pair of homoclinic orbits

$$q_h^\pm(t, \theta_0) = (\pm 2 \tan^{-1}(\sinh t), \pm 2 \operatorname{sech} t, \frac{h_0 - 1}{\omega}, \omega t + \theta_0)^T.$$

As $\mathbf{grad} K = (0, 0, 1, 0)^T$, the quantities $M^\pm(\theta_0, h_0)$ are immediately computed as the following absolutely convergent integrals ($h_0 > 1$):

$$\begin{aligned} & \frac{\sqrt{2(h_0 - 1)}}{\omega} \int_{-\infty}^{+\infty} \left[\frac{\sqrt{2(h_0 - 1)}}{\omega} \sin(\omega t + \theta_0) \right. \\ & \quad \left. \mp 2 \tan^{-1}(\sinh t) \right] \cos(\omega t + \theta_0) dt. \end{aligned} \quad (8)$$

The first term is odd and thus vanishes. Using integration by parts to simplify the second term yields the expression

$$M^\pm(\theta_0, h_0) = \pm \frac{\sqrt{2(h_0 - 1)}}{\omega^2} \times \int_{-\infty}^{+\infty} \operatorname{sech}(t) \sin(\omega t + \theta_0) dt,$$

which can be evaluated using the method of residues as

$$M^\pm(\theta_0, h_0) = \pm 2\pi \frac{\sqrt{2(h_0 - 1)}}{\omega} \operatorname{sech}\left(\frac{\pi\omega}{2}\right) \sin(\theta_0).$$

An infinite sequence of simple zeros of $M^\pm(\theta_0, h_0)$ guarantees the existence of transversal homoclinic orbits on each energy surface $h_0 > 1$, for $\varepsilon \neq 0$ sufficiently small.

MIXING

The word *mixing* is used both as a general term defining the operation of putting two or more substances together in order to achieve uniformity and as a mathematical term defining the property of random processes. Mixing as an operation is widespread as both a natural phenomenon and an industrial process. Putting milk into coffee, preparing cement, and pushing a car accelerator pedal involve mixing liquids, granular materials, and gases. On a molecular scale, it is diffusion that provides mixing. When diffusion is caused solely by the gradient of concentration $\theta(\mathbf{r}, t)$, it is described by the second-order partial differential equation

$$\frac{\partial \theta}{\partial t} = \text{div}(\kappa \nabla \theta). \quad (1)$$

When the diffusivity κ is constant, (1) is a linear parabolic equation which can be solved by

using the Green function: $\theta(\mathbf{r}, t) = (4\pi\kappa t)^{-d/2} \times \int \exp[-(\mathbf{r} - \mathbf{r}')^2/4\kappa t] \theta(\mathbf{r}', 0) d\mathbf{r}'$.

The diffusivity of gases in gases is of order $10^{-1} \text{ cm}^2 \text{ s}^{-1}$, so it would take many hours for an odor to diffuse across the dinner table. Similarly, to diffuse salt to a depth of 1 km in the ocean molecular diffusion would take 10^7 years. It is the motion of fluids that provides large-scale mixing in most cases. In a moving fluid, θ satisfies the advection-diffusion equation:

$$\frac{\partial \theta}{\partial t} + (\mathbf{v} \cdot \nabla) \theta = \text{div}(\kappa \nabla \theta). \quad (2)$$

If the velocity gradient is λ then one can define a diffusion scale $r_d = \sqrt{\kappa/\lambda}$ comparing advective and diffusive terms in (2). Fluid motion and molecular diffusion provide for mixing at the scales respectively larger and smaller than r_d . Inhomogeneous flow brings into contact fluid parcels with different values of θ thus producing large gradients that are then eliminated by molecular diffusivity. How fast mixing proceeds and how concentration variance decays in time depends on how inhomogeneous the flow is.

When a velocity field fluctuates, the simplest quantity (and often most important) is the concentration averaged over velocity, $\langle \theta(\mathbf{r}, t) \rangle$. The behavior of this quantity is determined by the properties of Lagrangian velocity $\mathbf{V}(t) = \mathbf{v}[\mathbf{q}(t), t]$, which is taken on the trajectory that satisfies $d\mathbf{q}/dt = \mathbf{v}[\mathbf{q}(t), t]$. For times longer than the Lagrangian correlation time, $\langle \theta(\mathbf{r}, t) \rangle$ also satisfies the diffusion equation

$$\left[\partial_t - (\kappa \delta_{ij} + D_{ij}) \nabla_i \nabla_j \right] \langle \theta(\mathbf{r}, t) \rangle = 0,$$

with so-called eddy diffusivity

$$D_{ij} = \frac{1}{2} \int_0^\infty \langle V_i(0) V_j(s) + V_j(0) V_i(s) \rangle ds.$$

If we release a single spot of, say, a pollutant, then its average position is given by $\langle \theta(\mathbf{r}, t) \rangle$. On the other hand, the evolution of the spot itself depends on the spatial properties of the velocity field. In considering hydrodynamic mixing at a given scale, one usually distinguishes between two qualitatively different classes of velocity fields: spatially smooth and nonsmooth. Velocity can be considered spatially smooth on a given scale if the velocity gradient does not change much across the scale. Comparing the inertial term $(\mathbf{v} \cdot \nabla) \mathbf{v}$ with the viscous term $\nu \Delta \mathbf{v}$ in the Navier-Stokes equation for fluid motion, one defines the viscous scale η similarly to r_d . Turbulent flows are smooth at scales smaller than η (viscous interval) and nonsmooth at larger scales (inertial interval). Fluid particles separate exponentially with time in smooth flows and according to power laws in nonsmooth flows.

Despite the fact that the fluid viscosity ν (momentum diffusivity) is caused by the same molecular motion as κ (diffusivity of a substance), their ratio varies

widely depending on the type of material. That ratio is called the Schmidt number, or Prandtl number when θ is temperature. The Schmidt number is very high for viscous liquids and also for colloids and aerosols, since the diffusivity of, say, micron-size particles (e.g., cream globules in milk and smoke in the air) is six to seven orders of magnitude less than the viscosity of the ambient fluid. In those cases, $r_d \ll \eta$. At scales less than η , the flow is spatially smooth, and the velocity difference between two fluid particles can be presented as $\mathbf{v}(\mathbf{q}_1, t) - \mathbf{v}(\mathbf{q}_2, t) = \hat{\sigma}(t)\mathbf{R}(t)$ so that the separation $\mathbf{R} = \mathbf{q}_1 - \mathbf{q}_2$ obeys the ordinary differential equation

$$\dot{\mathbf{R}}(t) = \sigma(t)\mathbf{R}(t),$$

leading to the linear propagation $\mathbf{R}(t) = W(t)\mathbf{R}(0)$. The main statistical properties of $\mathbf{R}(t)$ can be established at the limit when t exceeds the correlation time of the strain matrix $\hat{\sigma}(t)$. The basic idea (going back to the works of Lyapunov, Furstenberg, Oseledec, and many others and developed in the theory of dynamical chaos) is to consider the positive symmetric matrix $W^T W$ which determines R . The main result states that in almost every realization of $\hat{\sigma}(t)$, the matrix $t^{-1} \ln W^T W$ stabilizes as $t \rightarrow \infty$. In particular, its eigenvectors tend to d fixed orthonormal eigenvectors $\mathbf{f}_i$. To understand that intuitively, consider some fluid volume, say, a sphere, which evolves into an elongated ellipsoid at later times. As time increases, the ellipsoid is more and more elongated, and it is less and less likely that the hierarchy of the ellipsoid axes will change. The limiting eigenvalues

$$\lambda_i = \lim_{t \rightarrow \infty} t^{-1} \ln |W \mathbf{f}_i| \quad (3)$$

define the so-called Lyapunov exponents. The major property of the Lyapunov exponents is that they do not depend on the starting point if the velocity field is ergodic.

Consider now a pollutant spot with size l released within a spatially smooth velocity and assume that the Peclet number l/r_d is large. The above consideration shows, in particular, that the spot will acquire an ellipsoid form. The direction that corresponds to the lowest Lyapunov exponent (necessarily negative in an incompressible flow) contracts until it reaches r_d , and further contraction is stopped by molecular diffusion. Because the exponentially growing directions continue to expand, the volume grows exponentially and the value of θ inside the spot decays exponentially in time. For an arbitrary large-scale initial distribution of θ , the concentration variance decays exponentially in a spatially smooth flow because this is how fast velocity inhomogeneity contracts θ “feeding” molecular diffusion which eventually decreases the variance. Even though it is diffusion that diminishes θ and the rate of decay is independent of κ , it is usually of order of the typical velocity gradient.

If the Schmidt number is small while the Reynolds number of the flow is large then the velocity field at scales larger than r_d cannot be considered spatially smooth. That means that the velocity difference $\delta v(r)$, measured between two points distance r apart, scales as r^a with $a < 1$ (of course, δv is random and the statement pertains to the moments). For example, for the energy cascade in incompressible fluids, a is close to $1/3$. The equation $\dot{\mathbf{R}} = \delta \mathbf{v}(\mathbf{R}) \propto R^a$ suggests that interparticle distance grows by a power law: $R(t) \propto t^{1/(1-a)}$. The volume of any spot also grows so that scalar variance decays by a power law: $\langle \theta^2 \rangle \propto t^{d/(1-a)}$. Such estimates are supported by a rigorous theory only for a velocity field short-correlated in time. In this case, one can also show that the probability distribution $P(\theta, t)$ takes the self-similar form $t^{d/2(1-a)} Q(t^{d/2(1-a)}\theta)$ which is likely to be the case for a general scale-invariant velocity. On the contrary, $P(\theta, t)$ does not change in a self-similar way in a spatially smooth flow.

In finite vessels, the long-time properties of fluid mixing are usually determined by slowest parts, namely, the walls, where the velocity gradient may become zero, and corners with recirculating eddies.

In multiphase flows, not only mixing but also segregation can occur. The physical reason for that is a centrifugal force: when fluid streamlines are curved, heavier particles move out while lighter particles move in. It is a matter of everyday experience that air bubbles are trapped inside the sink vortex while heavy particles gather outside the vortices (which is used, in particular, for flow visualization).

Granular mixing is strikingly different from fluid mixing. In a granular flow, collisions of grains are inelastic and friction between grains makes it possible for static configurations (such as arches) to support a load and distribute stresses. As a result, granular motion has nonlocal properties, and no effective hydrodynamic description based on average over local kinetics (such as Equation (2)) is available. When a container partially filled with grains is vertically shaken with accelerations larger than the gravitational acceleration, convective rolls are observed with grains rising at the center and falling along the walls. Contrary to fluid convection, however, the grains move faster and mix better near the walls. Granular flows can also demonstrate segregation. The most celebrated example is the so-called Brazil nut effect whereby large particles (Brazil nuts) rise to the top of shaken container of mixed nuts.

The use of the term *mixing* in mathematics is based on the notion (introduced by Josiah Gibbs) that evolution is mixing when it leads asymptotically in time to some equilibrium invariant measure. Formally, one defines the evolution operator U_t acting on some phase space A and denotes the measure of any subset B as $P(B)$. The evolution is mixing if for any $B, C \in A$ one has $\lim_{t \rightarrow \infty} P(A \cap U_t B) = P(A)P(B)$. One can also define weak mixing property where

$\lim_{t \rightarrow \infty} t^{-1} \int P(A \cap U_s B) ds = P(A)P(B)$. Mixing of a random process or dynamical system means ergodicity, that is equality between temporal and phase space average.

MODULATED WAVES

The term *modulated waves* implies waves in which some parameters vary slowly in time or in space–time compared with the main (carrier) variables. The term *modulation* comes from acoustics (music) and radio engineering, where signals of the type

$$A(t) \cos[\omega_0 t + \varphi(t)] \quad (1)$$

have long been used for transmitting and processing information. Here, the carrier frequency ω_0 is constant with respect to time t , whereas the amplitude A and phase φ are slowly varying functions of time as compared with variations of the carrier oscillations described by the function $\cos(\omega_0 t)$. If only one of the parameters A and φ is variable, the terms *amplitude modulation* or *phase modulation* are used. A more general form is $A(t) \cos[\Phi(t)]$, where Φ is the full phase, so that the frequency $\omega(t) = d\Phi/dt$ is slowly varying. Although this case is called frequency modulation, the terms *phase* and *frequency modulation* describe essentially the same process.

For spatially varying signals, a natural generalization of that is a modulated quasiharmonic wave

$$A(\mathbf{r}, t) \cos[\omega_0 t + \varphi(\mathbf{r}, t)] \text{ or } A(\mathbf{r}, t) \cos[\Phi(\mathbf{r}, t)], \quad (2)$$

where A , φ , and $\partial\Phi/\partial t$ are slowly varying functions of time. In the spectral representation, the first of these expressions yields a narrow frequency spectrum as compared with the carrier frequency ω_0 , whereas the spectrum of the second expression can be arbitrarily wide. The cause of wave modulation can be different: modulation in initial or boundary (signaling) conditions, slow variation of the medium parameters in time and space, attenuation, and amplification.

A typical case is a one-dimensional traveling wave when functions (2) depend on time t and one spatial coordinate x , for example,

$$A(x, t) \cos[\omega_0 t - k_0 x + \varphi(x, t)], \quad (3)$$

where k_0 is the wave number. At constant A and φ , this wave is a sinusoid propagating with phase velocity $c_{ph} = \omega_0/k_0$. If the envelope A and phase φ (sometimes called phase envelope, implying all slowly varying parameters of a modulated wave propagate as envelope waves) are slowly varying in space time, and the medium is linear, then up to some distance, they propagate as a wave, with the group velocity, $c_{gr} = d\omega_0/dk_0$, where the dependence between ω_0 and k_0 (dispersion equation) is determined by the properties of the medium. Phase and group velocities are equal only in a nondispersive media, otherwise they are different. At even larger times in a dispersive medium, the wave envelopes are deformed. In particular, a finite-length impulse broadens and turns into a frequency-modulated wave in which each group propagates at its local group velocity depending on its frequency. Such dynamics can be represented by trajectories of groups on the (x, t) plane which are somewhat analogous to spatial rays in geometrical optics or geometrical acoustics and are called space-time rays.

In nonlinear dispersive media, the propagation of envelopes of a modulated dispersive wave is determined not only by its frequency but also by its amplitude (intensity). The interplay of these two factors—dispersion and nonlinearity—results in a variety of scenarios (Ostrovsky & Potapov, 1999; Scott, 1999; Whitham, 1974).

Under definite conditions, first, a non-modulated quasiharmonic wave can be unstable with respect to small modulating perturbations of its amplitude and phase (modulational or Benjamin–Feir instability). In other cases, modulation does not grow, but the envelope distorts with formation of steep (at a modulation scale) fronts (self-steepening). Finally, a steady propagation of envelopes is possible in the form of envelope solitons and envelope shocks.

The notion of modulation can be extended to significantly nonharmonic processes, such as cnoidal

Figure 1. An example of a quasi-harmonic modulated wave.

waves which are typical elliptic function solutions of nonlinear wave equations. Also, in these solutions, slow modulation of their parameters (amplitude and period) in space and time can occur. Let the nonmodulated wave have the form $F(\omega t - kx, A_i)$, where F is a periodic function, the A_i are parameters defining the solution (such as the wave amplitude), and ω and k are effective frequency and wave number defined via the wave period T and its wavelength, Λ , as $\omega = 2\pi/T$ and $k = 2\pi/\Lambda$. Then at slow modulation of these parameters, the wave has the form

$$F[\theta(x, t), A_i(x, t)], \quad (4)$$

where F is a periodic function, A_i are slowly varying functions of x and t , and the phase θ is defined in such a way that $\omega = \partial\theta/\partial t$ and $k = -\partial\theta/\partial x$ are also slowly varying functions. Due to these slow variations, the wave profile can change continuously from an almost sinusoidal wave up to a train of pulses similar to solitary waves or solitons, as the modulus of the elliptic function increases.

Mathematical descriptions of modulated waves are based on asymptotic perturbation theory (Ostrovsky & Gorshkov, 2000) or on more heuristic descriptions. A rather general approach (Whitham's method) starts with a Lagrangian description of a wave field and employs the corresponding variational principle (Whitham, 1974; Ostrovsky & Potapov, 1999; Scott, 1999). For modulated quasi-periodic waves, substituting an expression of type (4) into the Lagrangian (L) and averaging over θ , one obtains an averaged Lagrangian $\mathcal{L}$ depending only on slowly varying parameters, A_i , ω , and k . Considering θ and A_i as new canonical variables, one then obtains from $\mathcal{L}$ variational equations describing the relation among A_i , ω , and k , and their variations in space and time.

This and other averaging methods can work for both nonharmonic nonlinear waves and for weakly nonlinear (or just linear) waves (2) or (3). For narrow-spectrum waves such as (3), a more detailed description can be developed that goes beyond the framework of space-time geometrical optics and takes into account time analogs of wave diffraction. In particular,

Figure 2. An example of a nonsinusoidal modulated wave.

the nonlinear Schrödinger equation has been obtained to describe such processes. This approach is useful, for example, for the study of envelope solitons having applications in nonlinear optics and for deep water waves.

Moreover, the evolution of a single soliton with slowly varying parameters (due to small losses or smooth inhomogeneities) can be represented in the form of Equation (4), where F is a localized function rather than a periodic one (Ostrovsky & Gorshkov, 2000; Ostrovsky & Potapov, 1999). This class of processes can also be referred to as modulation, and perturbation methods for slowly varying solitary waves have been constructed. Thus, such processes as damping, propagation in inhomogeneous media, and solitary-wave interactions have been analyzed. In the latter case, solitary waves can interact as particles (hence the term *soliton*) with different types of interactions, including repulsion when solitons retain their parameters after interaction and attraction when they may form an oscillating bound state or breather.

Finally, the term *modulation* can be extended to a wave that does not have a prescribed shape but a continuously but slowly distorting profile. A typical example is weakly nonlinear waves in nondispersive media—such as acoustic waves in fluids—where a cumulative steepening of a wave profile can occur up to the formation of weakly nonlinear shock waves. Provided the distortion is small at a wavelength scale, one can also refer to wave profile modulation.

MOLECULAR DYNAMICS

Molecular dynamics (MD) refers to a family of computational methods aimed at simulating macroscopic behavior (thermodynamic or hydrodynamic) through the numerical integration of the classical equations of motion of a microscopic many-body system. Macroscopic properties are expressed as functions of particle coordinates and/or momenta, which are computed along a phase space trajectory generated by classical dynamics. At the core of the method is the assumption that over long times the system will reach an equilibrium state, or alternatively a steady state when simulating hydrodynamic conditions, in which temporal averages can be identified with statistical ensemble averages. This requires that mixing and Lyapunov instability be present in the phase space trajectories.

The field of MD simulations was born in the 1950s out of computational studies of the approach to equilibrium in a hard sphere system by B.J. Alder and T.E. Wainwright in 1957 (see Cicotti et al. (1987) for a collection of seminal works illustrating the development and application of MD simulations). The first MD simulation employing continuous potentials was used to study radiation damage in a two-dimensional solid by Gibson et al. (1960). The first application of the methodology as it is used today, to an atomic fluid modeled by continuous potentials in three dimensions, was a study of structural and dynamical aspects of liquid argon by A. Rahman in 1964. Subsequently, MD simulations have been applied to the study of complex systems such as biomacromolecules and self-assembled systems, and to the elucidation of complex spatiotemporal phenomena in more simple systems. When performed under conditions corresponding to laboratory scenarios, molecular dynamics simulations can provide a detailed view of structure and dynamics at the atomic and mesoscopic levels that is not presently accessible by experimental measurements. The simulations can also be set to perform "computer experiments" that could not be carried out in the laboratory, either because they do

not represent natural behavior or because the necessary controls cannot be achieved. Lastly, MD simulations can be implemented as simple test systems for condensed matter theory. In order to realize this wide spectrum of applications, several issues concerning system modeling, dynamical generation of statistical ensembles, and efficient numerical integrators must be considered.

To set the stage, consider the evolution of an isolated system of N point particles. In three dimensions, the canonical description of such system is given by a set of $6N$ first-order differential equations for the particles' positions $\mathbf{r}(t) = \{\mathbf{r}_1 \dots \mathbf{r}_N\}$ and momenta $\mathbf{p}(t) = \{\mathbf{p}_1 \dots \mathbf{p}_N\}$. The dynamics of the i th particle can be written in Hamiltonian form as

$$\begin{aligned}\dot{\mathbf{r}}_i &= \frac{\partial \mathcal{H}}{\partial \mathbf{p}_i} = \frac{\mathbf{p}_i}{m}, \\ \dot{\mathbf{p}}_i &= -\frac{\partial \mathcal{H}}{\partial \mathbf{r}_i} = -\frac{\partial V(\mathbf{r})}{\partial \mathbf{r}_i}\end{aligned}\quad (1)$$

with the Hamiltonian given by

$$\mathcal{H}(\mathbf{r}, \mathbf{p}) = \sum_{i=1}^N \frac{\mathbf{p}_i^2}{2m_i} + V(\mathbf{r}), \quad (2)$$

where $V(\mathbf{r})$ is the potential. The phase space trajectory generated is constrained to a hypershell parametrized by the conserved total energy of the system $\mathcal{H}(\mathbf{r}, \mathbf{p}) = E$. Microcanonical ensemble averages are constructed by means of the corresponding probability density function. For any observable A , either explicitly time-dependent or independent, the microcanonical ensemble average is given by

$$\langle A \rangle = \frac{\int d\mu A(\mathbf{r}(t), \mathbf{p}(t)) \delta(\mathcal{H} - E)}{\int d\mu \delta(\mathcal{H} - E)}, \quad (3)$$

where $d\mu$ is the corresponding invariant measure, in this case $d\mu = d\mathbf{p} d\mathbf{r}$. The chaotic nature of the phase space trajectory, in the sense indicated previously, allows the identification of (3) with the temporal average over an equilibrated simulation of time-length T :

$$\bar{A} = \frac{1}{T} \int dt A(\mathbf{r}(t), \mathbf{p}(t)) = \langle A \rangle. \quad (4)$$

MD simulations use information (positions, velocities or momenta, and forces) at a given instant in time, t , to predict the positions and momenta at a later time, $t + \Delta t$, where Δt is the time step, usually taken to be constant throughout the simulation. Numerical solutions to the equations of motion are thus obtained by iteration of this elementary step. The most popular algorithms for propagating the equation of motion, or "integrators," are based on Taylor expansions of the positions (see Allen & Tildesley (1989) for a survey). For example, the Verlet algorithm uses the sum of third order expansions forward and backward in time of the

particle positions, $\mathbf{r}_i$,

$$\mathbf{r}_i(t + \Delta t) = \mathbf{r}_i(t) + \Delta t \mathbf{v}_i(t) + \frac{\Delta t^2}{2m_i} \mathbf{F}_i(t) + \frac{\Delta t^3}{6} \mathbf{b}_i(t) + \mathcal{O}(\Delta t^4), \quad (5)$$

$$\mathbf{r}_i(t - \Delta t) = \mathbf{r}_i(t) - \Delta t \mathbf{v}_i(t) + \frac{\Delta t^2}{2m_i} \mathbf{F}_i(t) - \frac{\Delta t^3}{6} \mathbf{b}_i(t) + \mathcal{O}(\Delta t^4), \quad (6)$$

where $\mathbf{v}_i$ is the velocity, $\mathbf{F}_i$ is the force, and $\mathbf{b}_i$ is the third derivative with respect to time, to obtain an equation for the predicted position that is accurate to third order in time (because of the cancellation of the terms containing odd powers of time):

$$\mathbf{r}_i(t + \Delta t) = 2\mathbf{r}_i(t) - \mathbf{r}_i(t - \Delta t) + \frac{\Delta t^2}{m_i} \mathbf{F}_i(t) + \mathcal{O}(\Delta t^4). \quad (7)$$

An equation for the velocities is obtained by subtracting the two expansions,

$$\mathbf{v}_i(t) = \frac{\mathbf{r}_i(t + \Delta t) - \mathbf{r}_i(t - \Delta t)}{2\Delta t} + \mathcal{O}(\Delta t^3). \quad (8)$$

Note that, according to Equation (7), the velocities are not necessary for prediction of the positions. Because the velocities are determined at time t while the positions are determined at time $t + \Delta t$, calculation of velocity-dependent quantities (e.g., the kinetic energy) coincident with the predicted positions is awkward. The Verlet algorithm can be modified to synchronize the prediction of the positions and velocities. One popular modification, the “velocity Verlet” algorithm, is described below.

A general approach to the development of MD integrators has been formulated based on the Liouville operator formalism of Hamiltonian mechanics, in which Hamilton’s equations of motion (Equations (1)) are recast as

$$\dot{\Gamma} = iL\Gamma. \quad (9)$$

Here, Γ is a $6N$ -dimensional phase vector of the N particle coordinates and momenta (or velocities), and iL is the Liouville operator

$$iL = \dot{\Gamma} \cdot \nabla_{\Gamma} = \sum_{i=1}^N \mathbf{v}_i \cdot \nabla_{\mathbf{r}_i} + \sum_{i=1}^N \left[\frac{\mathbf{F}_i(\mathbf{r})}{m_i} \right] \cdot \nabla_{\mathbf{v}_i}. \quad (10)$$

The formal solution to Equation (10) is

$$\Gamma(t) = \exp(iLt)\Gamma(0). \quad (11)$$

In practice, this is not useful because the action of the propagator, $\exp(iLt)$, on the phase vector cannot be determined analytically. However, it is possible to derive accurate short-time approximations to the

propagator, whose action can be evaluated analytically, by factorizing the propagator. To this end, Equation (11) is rewritten so that the trajectory from 0 to t is generated in a sequence of P discrete time steps, $\Delta t = t/P$:

$$\Gamma(t) = \prod_{j=1}^P \left(\exp(iL_s \Delta t) \right) \Gamma(0). \quad (12)$$

Then the Trotter factorization may be used to decompose the propagator (Tuckerman & Martyna, 2000):

$$\exp(iL\Delta t) = \exp\left(iL_1 \frac{\Delta t}{2}\right) \exp(iL_2 \Delta t) \exp\left(iL_1 \frac{\Delta t}{2}\right) + \mathcal{O}(\Delta t^3) \quad (13)$$

giving an approximate, short-time evolution operator that is time-reversible and has the same accuracy as typical MD integrators. The operators iL_1 and iL_2 are chosen so that their action on the phase vector can be determined analytically, with the restriction that $iL_1 + iL_2 = iL$. For example, applying (13) to the phase vector, $\Gamma = (\mathbf{r}, \mathbf{v})$ (written here and in what follows in terms of velocities), with

$$iL_1 = \sum_{i=1}^N \left[\frac{\mathbf{F}_i(\mathbf{r})}{m_i} \right] \cdot \nabla_{\mathbf{v}_i}, \quad (14)$$

$$iL_2 = \sum_{i=1}^N \mathbf{v}_i \cdot \nabla_{\mathbf{r}_i} \quad (15)$$

gives the velocity Verlet integrator:

$$\mathbf{r}_i(t + \Delta t) = \mathbf{r}_i(t) + \Delta t \mathbf{v}_i(t) + \frac{\Delta t^2}{2m_i} \mathbf{F}_i(\mathbf{r}(t)), \quad (16)$$

$$\mathbf{v}_i(t + \Delta t) = \mathbf{v}_i(t) + \frac{\Delta t}{2m_i} [\mathbf{F}_i(\mathbf{r}(t)) + \mathbf{F}_i(\mathbf{r}(t + \Delta t))]. \quad (17)$$

In practice, computing meaningful time averages according to (4) requires sufficient sampling of an already equilibrated trajectory. This determines the total simulation time T . Once a model system and a dynamical system (i.e., an ensemble average) have been chosen, computational efficiency will rely on the choice of the numerical integrator. The total real computational time will depend on how many steps are required to reach the total time-length T . The choice of the time step size depends on the rate of accumulation of numerical errors as evaluated by the tolerance ΔE for the conserved quantity E . In molecular systems, the time step is determined by the highest frequency vibrational mode in the system. A rule of the thumb, is that, for numerical stability, one vibrational period should be covered by roughly 20 time steps. A popular approach to increasing the time step in MD simulations of molecular systems is to use holonomic constraints to freeze the motion of the

highest frequency bonds, or all of the bonds altogether. This is considered acceptable practice for most applications because the bond stretching motion is effectively decoupled from the other degrees of freedom that are typically of greater interest. To solve the equations of motion in the presence of constraints, the Lagrangian formalism of classical mechanics is used, and the constraint forces are expressed in terms of undetermined multipliers. There are a variety of algorithms for solving the resulting constraint equations and integrating the equations of motion (see Allen & Tildesley, 1989). The details depend on the choice of the integrator. The most popular are iterative methods known as SHAKE, designed to work with the Verlet integrator, and RATTLE, designed to work with the velocity Verlet integrator.

The utility of the constraint method rests on the fact that the fastest degrees of freedom place an upper bound on the time step, and the time step can therefore be increased if the fastest degrees of freedom are eliminated (constrained). A more general approach is based on the premise that the forces associated with different degrees of freedom evolve on different time scales, and the slower forces do not need to be computed as often as the faster forces. It turns out, for molecular systems, that the fastest forces, those associated with intramolecular interactions, require the least computational effort to evaluate ($\mathcal{O}(N)$), while the slowest forces, those associated with nonbonded interactions, require the most computational effort ($\mathcal{O}(N^2)$). Thus, in the interest of computational efficiency, it is clearly advantageous to calculate the rapidly evolving forces at each elementary time step, and only calculate the slowly evolving forces at a larger time interval that is several times the elementary time step. This is the essence of multiple time step MD (see Tuckerman & Martyna (2000) for a review), which is briefly summarized below.

Suppose that the total force on the particle i may be written

$$\mathbf{F}_i = \mathbf{F}_i^{\text{fast}} + \mathbf{F}_i^{\text{slow}}, \quad (18)$$

where $\mathbf{F}_i^{\text{fast}}$ and $\mathbf{F}_i^{\text{slow}}$ are the parts of the force that change rapidly and slowly, respectively. Now, according to Equation (13), we may write

$$\begin{aligned} \Gamma(t + \Delta t) &= \{\exp(iL_3\Delta t/2)[\exp(iL_1\delta t/2)\exp(iL_2\delta t) \\ &\quad \times \exp(iL_1\delta t/2)]^n \exp(iL_3\Delta t/2)\} \mathbf{x}(t) + \mathcal{O}(\Delta t^3), \end{aligned} \quad (19)$$

where iL_2 is as before and

$$iL_1 = \sum_{i=1}^N \left[\frac{\mathbf{F}_i^{\text{fast}}(\mathbf{r})}{m_i} \right] \cdot \nabla_{\mathbf{v}_i}, \quad (20)$$

$$iL_3 = \sum_{i=1}^N \left[\frac{\mathbf{F}_i(\mathbf{r}) - \mathbf{F}_i^{\text{fast}}(\mathbf{r})}{m_i} \right] \cdot \nabla_{\mathbf{v}_i} \quad (21)$$

with $\delta t = \Delta t/n$. Thus, to evolve the system from time t to $t + \Delta t$ in one step of an MD simulation, the total force needs to be evaluated only once, and the fast component of the force n times. The small time step, δt , is determined by the time scale of the fast forces. As the computational effort required to evaluate the fast component of the force is negligible compared with that required for the slow force, this scheme results in nearly a factor of n decrease in computational effort. The resulting algorithm is straightforward to implement because each action of the evolution operators translates directly into velocity Verlet-like integration steps (Tuckerman & Martyna, 2000).

The majority of microscopic systems modeled by MD simulations are collections of atoms or molecules in a condensed phase. The usual quantum mechanical treatment of molecular systems assumes that the problem is separable between electronic and nuclear (or ion-core) degrees of freedom. Within this context, the most common approach in MD simulations is to consider the classical limit for the nuclear degrees of freedom. Thus, the phase space trajectory describes the dynamics of the atomic nuclei as classical point particles, while the electronic degrees of freedom are accounted for by the interaction potential $V(\mathbf{r})$. There is not a single prescription for choosing the form of the potential energy function and determining its parameters. In general, analytical forms for model systems are taken from molecular mechanics, and the specific parameters are dependent on the kind of system that is being modeled. For simple systems, the available information from zero-temperature electronic structure calculations is directly fitted to a convenient analytical function. For complex systems, electronic structure calculations for small molecular moieties are complemented with relevant experimental data pertinent to the phase being modeled. For a detailed overview of commonly used empirical potentials, see Leach (2001).

Although the number and nature of the potential energy terms varies from one application to the next, the potential for an arbitrarily complicated molecule such as a polymer is generally written as the sum of “bonded” and “nonbonded” terms. The bonded terms include energy penalties, usually represented by harmonic potentials, for deforming chemical bonds and the angles between bonds from their equilibrium values, as well as periodic potentials to describe the energy change as a function of the torsion (dihedral) angle about rotatable bonds. The bonded terms are usually taken to be diagonal, that is, there are no terms describing coupling between deformations of bonds and angles, bonds and torsions, etc. These off-diagonal terms are important for accurate reproduction of vibrational properties, as are anharmonic terms (e.g., cubic, quartic). The nonbonded terms, as the name suggests, describe the interactions

between atoms in different molecules, or interactions within a molecule that are not completely accounted for by the bonded terms; that is, they are separated by more than two bonds. The nonbonded terms are typically assumed to be pairwise-additive functions of interatomic separation, r , and include van der Waals interactions and Coulomb interactions in polar or charged molecules in which the charge distribution is represented by partial charges (usually placed on the atoms). The van der Waals interactions include a term that is strongly repulsive (exponential or inverse 12th power of r), and a weakly attractive dispersion term (e.g., inverse 6th power of r , representing the induced dipole-induced dipole interaction). A popular form for the van der Waals interactions is the Lennard-Jones ("12-6") potential:

$$V(r) = 4\varepsilon \left(\left(\frac{\sigma}{r} \right)^{12} - \left(\frac{\sigma}{r} \right)^6 \right) \quad (22)$$

Here, ε is the depth of the minimum, and σ is where the potential crosses zero and is a measure of the van der Waals diameter of the atom.

The number of bonded interactions grows in proportion to N , the number of atoms in the system, while the number of nonbonded interactions grows as N^2 . Therefore, most of the computer time used for an MD simulation is spent on the evaluation of the nonbonded energies and forces. To reduce this burden, van der Waals interactions are typically ignored beyond some "cutoff" distance, usually around two or three atomic diameters. However, because the Coulomb potential is long-ranged, it is dangerous to truncate the electrostatic interactions. In condensed phase systems modeled using periodic boundary conditions (to eliminate surface effects in simulations of small systems that are meant to be in a bulk environment), the Ewald method can be used to sum all of the electrostatic interactions in an infinite, periodically replicated system. Details on the implementation of the Ewald sum may be found in Allen & Tildesley (1989).

Although MD simulations are most conveniently carried out in the microcanonical ensemble, there are disadvantages to doing so. An important aspect of performing simulation studies is to calculate experimentally measurable properties for comparison with measurements made at particular thermodynamic state points. Most experiments are carried out under the conditions of constant N and temperature, and either constant pressure or constant volume, that is, in the isobaric-isothermal or canonical statistical mechanical ensembles. In microcanonical simulations, the temperature and pressure are computed via averages of the kinetic energy and virial, respectively, and it is not known until after the simulation has been completed whether it was run at the desired state point. Moreover, in the canonical and isobaric-isothermal

ensembles, the characteristic thermodynamic potentials are the Helmholtz free energy, $F(N, V, T)$, and Gibbs free energy, $G(N, P, T)$, respectively, and these free energies are easier to calculate from MD trajectories (see Frenkel & Smit (1996) for a discussion of methods for free energy calculations) than the entropy, $S(N, V, E)$, which is the characteristic thermodynamic potential of the microcanonical ensemble. In addition, constant pressure simulations are especially useful when the density of the system is not known a priori.

Several techniques for generating trajectories in ensembles other than the microcanonical ensemble have been developed (see Allen & Tildesley (1989) for an overview and Ciccotti et al. (1987) for a collection of key papers). The most powerful techniques are based on the concept of an "extended system" (ES), in which the atomic positions and momenta are supplemented by additional dynamical variables representing the coupling of the system to an external reservoir. For example, in the first application of the extended system concept to a simulation at constant pressure by H.C. Andersen in 1980, the system volume was taken to be a dynamical variable to simulate coupling to a pressure reservoir. In the Nosé implementation of constant temperature MD, a time-scaling "thermostat" variable was introduced. M. Parrinello and A. Rahman (1981) generalized Andersen's constant pressure method to allow the simulation cell to change shape as well as size by making the elements of the cell matrix dynamical variables. In these initial formulations of the ES concept, the additional dynamical variables were assigned fictitious kinetic and potential energies, and their equations of motion were derived using the Lagrangian formalism. Note that the choice of the form of the equations of motion for the additional degrees of freedom is not arbitrary, but rather should be made so that the resulting phase space distribution function is that of the desired ensemble. The Lagrangian formalism is not always the most convenient for handling extended systems. A more general approach is based on the formalism of non-Hamiltonian dynamics (Tuckerman & Martyna, 2000), which is sketched below. This approach was pioneered by W.G. Hoover, who rewrote the equations of motion for the Nosé thermostat in non-Hamiltonian form, leading to a much more straightforward implementation of constant temperature MD that was subsequently referred to as the Nosé-Hoover thermostat.

In the non-Hamiltonian dynamics approach, the equations of motion for the ES variables and a conserved Hamiltonian-like quantity, H' , which includes terms for the kinetic and potential energies of the ES degrees of freedom, are chosen together such that the microcanonical distribution function generated by the extended system dynamics

is formally equivalent (within a normalization constant) to the desired phase space distribution function of the atoms (e.g., canonical, isobaric-isothermal). The "non-Hamiltonian" resides in the fact that the necessary equations of motion cannot be derived from H' , as in the case of Hamilton's equations (see Equations (1)). A complication that arises for non-Hamiltonian systems is that the phase space compressibility,

$$\kappa = \nabla_{\Gamma} \cdot \dot{\Gamma}, \quad (23)$$

where Γ is now the $6N + 2M$ dimensional vector of coordinates and momenta (or velocities) of the N particles and M extended system variables, does not vanish as it does for Hamiltonian systems. Consequently, a metric factor must be included in the phase space measure,

$$d\mu = \sqrt{g(\Gamma, t)} d\Gamma, \quad (24)$$

where

$$\sqrt{g(\Gamma, t)} = \exp[-w(\Gamma, t)], \quad (25)$$

$$\frac{dw}{dt} = \kappa, \quad (26)$$

so that the extended system phase space volume is conserved (i.e., Liouville's theorem is obeyed). Reversible, multiple time step integrators for extended system (Martyna et al., 1996) and non-equilibrium (Mundy et al., 2000) dynamics have been derived based on non-Hamiltonian mechanics using the Liouville operator formalism illustrated above for microcanonical dynamics.

In extended system MD simulations with temperature and pressure control, the instantaneous temperature (kinetic energy) and pressure (virial) fluctuate, and it is their average values that are equal to the values imposed by the thermal and pressure reservoirs. There are two other commonly employed approaches to temperature and pressure control (see Allen & Tildesley (1989) for a survey). In one class of methods, the instantaneous temperature and pressure are constrained to constant values. For large systems, the imposition of constraints is reasonable because fluctuations are small. By introducing Lagrange multipliers and applying Gauss's principle of least constraint, the constraints are applied in such a way so as to minimize the change in dynamics. The resulting phase space distribution functions are equal to the desired ones, multiplied by delta functions that account for the constraints on the temperature and pressure. Another technique is referred to as "coupling to an external bath," where the "bath" can be a temperature and/or pressure reservoir. This scheme drives the system to the desired temperature (pressure) at a rate determined by a preset temperature (pressure) relaxation time by scaling the velocities (volume and coordinates) at each time step. This method has the advantage that it is easily implemented, and the disadvantage that it does

not generate states in any known statistical mechanical ensemble.

To date, most MD simulations have been driven by forces that were derived from assumed, empirical potentials. About two decades ago, the scope of MD simulations was greatly expanded by the introduction of a method by Car & Parrinello (1985) that, rather than relying on an empirical potential, utilizes interatomic potentials computed directly from the electronic structure which evolves simultaneously with the nuclear configuration. Thus, changes in electronic polarization and the possibility of chemical transformations are naturally included in the simulation. To this end, the wave function is expanded in a basis set, the expansion coefficients are treated as dynamical variables in an extended system Lagrangian, and the resulting equations of motion adiabatically propagate the electronic orbitals with respect to the nuclei, so that they remain on the ground state Born-Oppenheimer surface at each time step. Consequently, the need to solve the computationally burdensome electronic structure problem (self-consistent field) is avoided, and it is feasible to generate trajectories of sufficient length to study phenomena that were previously impossible to simulate. For technical details on the implementation of this so-called "ab initio MD" method, see Marx & Hütter (2000). Although the size of system (on the order of 100 atoms) and the length of trajectory (roughly tens of picoseconds) that can be simulated presently by ab initio MD are modest compared with simulations based on empirical potentials, it is clear that, as computational resources continue to evolve, applications of ab initio MD will become more and more prevalent and compelling.

MONODROMY PRESERVING DEFORMATIONS

Suppose $z \mapsto A(z)$ is a $p \times p$ matrix valued meromorphic function (analytic except for a finite number of poles) on the Riemann sphere (also called a “complex projective one space” and denoted as $\mathbf{P}^1$) with poles at the points a_v , $v = 1, \dots, n$. Suppose Ψ is a fundamental solution for the linear system,

$$\frac{d\Psi}{dz} = A(z)\Psi, \quad (1)$$

defined in a neighborhood of a regular point, a_0 . Analytic continuation of the fundamental solution along a closed curve γ which begins and ends at a_0 produces a change,

$$\Psi \rightarrow \Psi M_\gamma,$$

where M_γ is the *monodromy* associated with the path γ and the fundamental solution Ψ . The constant matrix M_γ depends only on the homotopy type of γ , and the map $\gamma \mapsto M_\gamma^{-1}$ is a representation of the fundamental group $\pi_1(\mathbf{P}^1 \setminus \{a_v\}, a_0)$ called the monodromy representation of the differential equation.

In the 1850s, Bernhard Riemann solved the connection problem for solutions to the hypergeometric equation by exploiting the monodromy representation. The hypergeometric equation is the family of second-order equations on $\mathbf{P}^1$ with three regular singular points, and the connection problem is to understand how the local series solutions defined near the singularities are related to one another by analytic continuation. Riemann made some further speculations about monodromy representations, and (inspired by Riemann's work) David Hilbert asked if any representation of $\pi_1(\mathbf{P}^1 \setminus \{a_v\}, a_0)$ might be realized as the monodromy representation of a suitable differential equation. This is the 21st in the list of problems presented by Hilbert at the International Congress of Mathematicians in 1900. It always has a solution for differential equations with regular singular points (Plemelj, 1963), but it does not always have a solution

if the differential equation is required to have simple poles. The book by Anasov and Bolibruch (1994) has a careful discussion of the history of this problem and its solution.

Suppose that the matrix $A(z)$ has simple poles,

$$A(z) = \sum_{v=1}^n \frac{A_v}{z - a_v}, \quad \text{with } \sum_{v=1}^n A_v = 0. \quad (2)$$

The second condition guarantees that ∞ is either a simple pole or a regular point. For simplicity, we also suppose that for each v no pair of eigenvalues for A_v differ by an integer. In this *nonresonant* case, the differential equation (1) is holomorphically equivalent to the differential equation,

$$\frac{d\Phi}{dz} = \frac{A_v}{z - a_v} \Phi, \quad (3)$$

in a neighborhood of $z = a_v$. In 1912, Ludwig Schlesinger asked how the residue matrices A_v should depend on the pole locations $a = (a_1, a_2, \dots, a_n)$ in order that the monodromy representation remain unchanged. In case ∞ is a regular point, he discovered that the matrices A_v must satisfy a nonlinear differential equation,

$$dA_\mu = - \sum_{v \neq \mu} \frac{A_\mu A_v - A_v A_\mu}{a_\mu - a_v} d(a_\mu - a_v).$$

This equation is known as the Schlesinger equation and is an example of a *monodromy preserving deformation*.

Schlesinger's treatment of the existence question for such deformations was clarified in the work of Malgrange (1983b). Let $D_{\mu\nu} = \{a \in \mathbf{C}^n : a_\mu = a_\nu\}$ denote the set of points in $\mathbf{C}^n$ where the μ and ν poles collide—evidently such points are singular points for the Schlesinger equations. Malgrange showed that if one starts with a monodromy representation that is realized for a differential equation with simple poles at a_v^0 and residues A_v^0 , then the deformation equation has a solution $A_v(a)$ which is analytic on the simply connected covering of $\mathbf{C}^n \setminus \bigcup D_{\mu\nu}$ except possibly for poles along a hypersurface in this space. He also showed that the hypersurface on which the solutions $A_v(a)$ has poles consists of those points for which a variant of the Riemann–Hilbert problem fails to have a solution. It is simplest to describe this variant in the nonresonant case (although Malgrange does not make this assumption). The point a will be a pole of $A_v(a)$ provided that it is not possible to find a differential equation with simple poles at a_v for $v = 1, 2, \dots, n$ which reproduces the monodromy representation of the original equation,

$$\frac{d\Psi}{dz} = \sum_{v=1}^n \frac{A_v^0}{z - a_v^0} \Psi,$$

and is in the local holomorphic equivalence class of

$$\frac{d}{dz} - \frac{A_v^0}{z - a_v}$$

near $z = a_v$. It is possible that a given monodromy representation can be realized by a differential equation with simple poles without being able to specify the local holomorphic equivalence classes (see Bolibruch, 2002).

Nonlinear differential equations in the complex plane have the property that solutions can develop singularities away from the manifest singularities of the equations. The location of singularities of this sort depends on the initial conditions for the differential equation; thus, such points are called movable singularities. Differential equations with solutions whose only movable singularities are poles are said to have the Painlevé property. Paul Painlevé and Bertrand Gambier classified the simplest such nonlinear equations and determined six new families of transcendental functions that arise in the integration of these differential equations—now referred to as Painlevé I–VI (see Ince, 1956). Schlesinger understood, and as noted above, Malgrange proved that the Schlesinger equation has the Painlevé property. In a related development, Garnier (1912) showed that the Painlevé transcendents arise in the deformation of Fuchsian equations. Later, Jimbo, & Miwa (1981) showed how to obtain all six of the Painlevé equations by suitable specialization of the Schlesinger equations for 2×2 matrix systems. Painlevé VI arises for a linear system with simple poles of the type considered by Schlesinger. The other Painlevé equations arise by successive scaling that introduces irregular singularities and requires an extension of the Schlesinger analysis that was accomplished by Miwa, Jimbo, and Ueno in Jimbo, et al. (1981). Importantly, finding such representations for Painlevé equations is analogous to finding Lax pair representations for nonlinear equations such as the KdV equations (see Kapaev, 2002; Deift et al., 1999).

Flashka & Newell (1980) first considered a generalization of the notion of monodromy preserving deformations to linear differential equations with higher rank singularities (equations with poles of order 2 or higher are said to have irregular singularities). More subtle local invariants, called Stokes multipliers, are fixed by the deformations, and in addition to the location of the singularities, the deformation parameters include formal expansion parameters that characterize the local asymptotics of solutions near the singularities. Based on Birkhoff's generalization of the Riemann–Hilbert problem (Birkhoff, 1913), Jimbo, Miwa, and Ueno (1981) generalized Flashka and Newell's work to the consideration of nonresonant differential equations with irregular singular points. They obtained the analogue of the Schlesinger

equations for generalized monodromy preserving deformations of these equations. They also introduced the notion of a τ -function for such deformations. They conjectured that the τ -function is a holomorphic function of the deformation parameters whose 0 set is the set of pole locations for the solutions to the deformation equations. Miwa (1981) later showed that the τ -function is holomorphic and the Painlevé property is satisfied for the deformation equations in the domain of convergence for his explicit solution of the Birkhoff–Riemann–Hilbert problem. Malgrange (1983b) established the full conjecture for regular singularities without restrictions.

Geometric Perspectives

Röhl (1957) formulated and solved a version of the Riemann–Hilbert problem on Riemann surfaces. The setting for the result involves vector bundles and holomorphic connections with singularities. Deligne (1970) developed a multidimensional generalization of the Riemann–Hilbert problem which took advantage of rather abstract categorical constructions. Malgrange (1983a) introduced Stokes' sheaves at irregular singular points to describe local holomorphic equivalence classes. More recently, progress in analyzing the local structure of differential equations at irregular singular points has come by introducing sophisticated ideas from algebraic geometry (see Varadarajan, 1996). Part of the impetus for these developments is the effort to achieve clarity in a subject that is subtle enough to have inspired the misinterpretation of fundamental results and even errors in proofs by such luminaries as George D. Birkhoff (see Anasov and Bolibruch (1994) for an account).

Among these developments, there is one geometric idea introduced by Röhl and more fully realized by Malgrange (1983c), which provides helpful insight into the nature of the Birkhoff–Riemann–Hilbert deformation problem introduced in Jimbo et al. (1981). Suppose that $a^0 = \{a_1^0, a_2^0, \dots, a_n^0\}$ is a collection of distinct points in $\mathbf{P}^1$ and $A^0(z)$ is a rational matrix valued function whose principal part at $z = a_v$ is

$$\frac{A_{r+1}^0}{(z - a_v)^{r+1}} + \frac{A_r^0}{(z - a_v)^r} + \dots + \frac{A_1^0}{z - a_v}.$$

The integer $r = r_v$ is called the rank of the singularity. Let

$$\nabla^0 = \frac{d}{dz} - A^0(z)$$

denote the associated connection. We will say that the connection ∇^0 is *nonresonant* if the leading coefficient A_{r+1}^0 has distinct eigenvalues at each of the singularities with the additional requirement that these eigenvalues do not differ by integers in case $r = 0$. Incidentally, much of the machinery that has been introduced to study

irregular singular points is devoted to understanding the substantial complications that arise for *resonant* connections (Varadarajan, 1996).

It is a result of Deligne (1970) that the holomorphic equivalence class of ∇^0 on the punctured sphere $\mathbf{P}^1 \setminus \{a_v^0\}$ is determined by its monodromy representation. On the other hand, in a neighborhood of each of the singularities, the connection ∇^0 belongs to a local holomorphic equivalence class of rank r connections. For nonresonant connections, this local equivalence class, is naturally a fiber bundle whose base consists of *diagonal* connections,

$$\frac{d}{dz} - \frac{H_r}{(z - a_v)^{r+1}} + \cdots + \frac{H_0}{z - a_v}, \quad (4)$$

whose leading coefficient, H_r , has distinct eigenvalues which do not differ by integers in case $r = 0$. For $r = 0$ the form (4) determines the local equivalence class, but for $r \geq 1$ the fibers in the bundle are essentially the Stokes multipliers, S . Each nonresonant connection ∇^0 has a *formal reduction* to a type (4) connection and the holomorphic equivalence class for ∇^0 is determined by this formal reduction together with the Stokes multipliers. The Stokes multipliers determine the relations between solutions to $\nabla^0 \psi = 0$ that are sectorially asymptotic to flat sections of the connection (4) (see Sibuya, 1977; Malgrange, 1983c).

Let t denote the collection of diagonal entries for all the fibers H_j . The fiber bundle of local holomorphic equivalence classes has a natural flat connection (it is a so-called local system (Varadarajan, 1996)) and we let $t \rightarrow \sigma(t)$ denote the flat (locally constant) section of this bundle normalized to give the class of ∇^0 at the parameter value t^0 which corresponds to ∇^0 . The generalized monodromy preserving deformation problem is to find a family of connections $\nabla(a, t)$ which reproduces the monodromy representation of ∇^0 in the punctured plane $\mathbf{P}^1 \setminus \{a_v\}$ and whose local holomorphic equivalence class at each a_j is the equivalence class associated with the value of the flat section $\sigma(t)$ (i.e., locally constant Stokes multipliers).

The version of the Birkhoff–Riemann–Hilbert problem relevant to this deformation problem is: Given a representation of $\pi_1(\mathbf{P}^1 \setminus \{a, a_0\})$ and an assignment of a compatible local holomorphic equivalence class of a type r_v connection to each of the points a_v , find a connection on the trivial bundle over $\mathbf{P}^1$ which reproduces this data (compatible means that the local monodromy at a_v should reproduce the monodromy coming from the representation). Because noncanonical choices must be made to define the Stokes multipliers, this version of the Birkhoff–Riemann–Hilbert problem is even complicated to state if the connection with local holomorphic equivalence classes is not understood. Based on ideas of Malgrange, it has been shown that the τ -function introduced by Miwa, Jimbo, and Ueno (1981) has zeros for the deformation

problem described above precisely when the associated Birkhoff–Riemann–Hilbert problem fails to have a solution (Palmer, 1999). It should also be mentioned that a crucial technique used both by Jimbo et al. (1981) and by Malgrange (1983b,c) has the prolongation of the connection originally defined on $\mathbf{P}^1$ to an integrable connection defined on $\mathbf{P}^1 \times \mathcal{D}$ where $\mathcal{D}$ is the space of deformation parameters. In this multidimensional setting, Malgrange adapts Rörhl’s technique to prove the existence of a prolongation for the original connection on a vector bundle. The solution of the original deformation problem depends on the triviality of certain restrictions of this vector bundle.

Applications

The Riemann–Hilbert problem and the Painlevé transcendents have generated a steady stream of papers over the years, but interest in monodromy preserving deformations was largely dormant in the period from the early 1920s to the late 1970s. A rebirth of interest in the subject dates from the surprising discovery by Wu, McCoy, Tracy, and Baruch (WMTB) (1976) that the two-point scaling function for the two-dimensional Ising model can be expressed in terms of a Painlevé transcendent of type III. The two-dimensional Ising model is a statistical model of magnetism which exhibits a phase transition in the infinite volume limit. It is so far the only model with a phase transition in which the correlation functions can be studied exactly in the infinite volume limit. The scaling limit that was investigated in Wu et al. (1976) examines the asymptotics of the spin correlations at the length scale of the correlation length (which tends to ∞) as the temperature approaches the critical point. Not only is this analysis important for an understanding of critical phenomena in statistical physics, but it was understood at about the same time that the mathematics of critical phenomena in statistical physics was recognized as the same as the mathematics of renormalization for quantum field theory.

In a remarkable series of papers (Sato et al., 1978, 1979a,b,c, 1980) starting in 1978, Sato, Miwa, and Jimbo found a context for the WMTB result by showing that the n -point correlation for the Ising model could be expressed in terms of the solutions to “monodromy preserving deformations” of the Euclidean Dirac equation (with a mass term). Note that the equation which is the analogue of the Dirac equation in the earlier development is not the differential equation (1) but the Cauchy–Riemann equation $\bar{\partial} \psi = 0$. The correlation functions in the Ising model were the inspiration for their introduction of the τ -function in other contexts. See Palmer & Tracy (1983), Palmer (1993), Palmer et al. (1994), and Palmer (2002) for further developments of these ideas. In Jimbo et al. (1980), Sato, Miwa, Jimbo, and Mori explained the use of their techniques to analyze the impenetrable Bose gas and incidentally

remarked on a connection with an important function in random matrix theory.

The analysis of correlations in integrable models has since been developed by Its et al. (1990), who also codified some of the ideas in a theory of completely integrable integral operators (Korepin et al., 1993). The connection between the random matrix theory and Painlevé functions has been systematically worked out by Tracy & Widom (1994, 1996), who independently developed an integral equation approach to the nonlinear “deformation” equations.

Jimbo (1982) used the monodromy preserving deformation representation of Painlevé functions and the notion of the τ -function to analyze the connection problem for Painlevé functions. The problem is to understand how different families of solutions to the Painlevé equations defined by local asymptotic developments at different singular points are related to one another. Somewhat earlier the connection problem for Painlevé III was worked out by McCoy, Tracy, and Wu (1977) where the answer has consequences for the short distance behavior of the scaling function. Its and Novokshenov (1986) have developed these ideas further.

Although not quite a development in monodromy preserving deformation theory, a “steepest decent” technique based on Riemann–Hilbert ideas has emerged in work of Deift, Zhou and Its that is effective for the asymptotic analysis of solutions to nonlinear equations that arise from spectral or monodromy preserving deformations (Its, 1981; Deift et al., 1997; Bleher & Its, 1999; Deift et al., 1999).

Painlevé functions were discovered in two-dimensional quantum gravity and connections with monodromy preserving deformations are discussed in Moore (1990). Painlevé functions also arise in two-dimensional topological field theory (Dubrovin, 1999).

Further developments are discussed in Harnad & Its (2002).

MONTE CARLO METHODS

Monte Carlo methods collectively refer to a set of computational tools based on random samples. These methods have a very long history that can be traced back to

biblical times although a systematic foundation was established only in the early days of electronic computing. A group of mathematicians and physicists of the Los Alamos project during World War II, in particular, John von Neumann, Nick Metropolis, Jeffrey Kahn, Enrico Fermi, Stan Ulam, and their collaborators, developed Monte Carlo methods for estimating eigenvalues of the Schrödinger equation and for studying random neutron diffusion in fissile material used in atomic bombs. Since then, Monte Carlo methods have found applications in a vast number of scientific disciplines and are, becoming increasingly popular with the advent of cheap and powerful computers.

Starting with a space $\mathcal{X}$, let $\varphi: \mathcal{X} \rightarrow \mathbb{R}$ be function and π be a probability density. In essence, Monte Carlo methods are concerned with

- **Integration:** Evaluate the expectation of φ under π ; that is,

$$I_{\pi}(\varphi) = \int_{\mathcal{X}} \varphi(x) \pi(x) dx. \quad (1)$$

- **Simulation:** Simulate some random samples $\{X_i\}_{i=1}^N$ distributed according to π .

Integration and simulation are essential elements of many scientific problems arising, for example, in statistical physics, statistics, engineering, and economics. The probability density π may correspond to a posterior density in the framework of Bayesian statistics or a Boltzmann–Gibbs distribution in equilibrium statistical thermodynamics.

In most applications, it is impossible to compute the expectations of interest in closed-form as the dimension of the space $\mathcal{X}$ is large; for example, $\mathcal{X} = \mathbb{R}^{1000}$ or $\mathcal{X} = \{-1, 1\}^{5000}$. Moreover, π is often only known up to a normalizing constant, that is,

$$\pi(x) = c f(x), \quad (2)$$

where $f: \mathcal{X} \rightarrow \mathbb{R}$ is known but c is unknown. Consequently, standard deterministic numerical integration schemes are very inefficient.

The basic idea of Monte Carlo methods is to compute the expectation(s) of interest in Equation (1) via random samples. Assume the random samples $\{X^{(i)}\}_{i=1}^N$ distributed according to π are available, then an estimate of $I_{\pi}(\varphi)$ can be given by the empirical average

$$\hat{I}_{\pi}(\varphi) = \frac{1}{N} \sum_{i=1}^N \varphi(X^{(i)}).$$

In other words, π is approximated by

$$\hat{\pi}(x) = \frac{1}{N} \sum_{i=1}^N \delta(x - X^{(i)}),$$

where $\delta(\cdot)$ is the Dirac delta function. This estimate has “good” theoretical properties. First, it is unbiased.

Second, if the samples $\{X^{(i)}\}_{i=1}^N$ are statistically independent, then the variance of this estimate is given by

$$\frac{\int [\varphi(x) - I_\pi(\varphi)]^2 \pi(x) dx}{N}; \quad (3)$$

that is, the convergence rate of the estimation error to zero is independent of the dimension of $\mathcal{X}$. If the numerator of (3) is “small”, then only a few hundreds/thousands of samples might be necessary to achieve a good precision even if $\mathcal{X} = R^{1000}$.

Thus far, it has been shown that estimates with good theoretical properties can be easily obtained from a large set of samples distributed according to the probability density of interest, but how to generate these samples? The Monte Carlo integration problem then becomes that of simulation. Generating samples from nonstandard probability distributions/densities only known up to a proportionality factor is a central problem in Monte Carlo methods.

In 1947, von Neumann, in a letter to Ulam, described an algorithm known as the Rejection Method, to simulate samples distributed according to a “target” probability density. Given a target probability density π that is only known up to a normalizing constant, that is, π is of the form in (2) and only f is known, one chooses a candidate density g that is easy to sample from and a number M satisfying $f(x) \leq M g(x)$ for any $x \in \mathcal{X}$. The algorithm proceeds as follows:

(a) Sample $X^* \sim g$ (“ $\sim$ ” is a standard notation for “distributed according to”) and compute

$$\alpha(X^*) = \frac{f(X^*)}{M g(X^*)}.$$

(b) Sample a uniform random variable U on $[0, 1]$. If $U \leq \alpha(X^*)$, return X^* otherwise go back to (a).

It can be easily verified that the accepted sample follows the target distribution π . The problem with this method is the difficulty in finding a candidate density g satisfying $f(x) \leq M g(x)$ that is easy to sample from. Moreover, even if such a g can be found, the acceptance probability is $(Mc)^{-1}$, which can be extremely low when $\mathcal{X}$ is a high-dimensional space. Consequently, the algorithm may take a long time to generate a single sample.

A more powerful class of algorithms are the Markov chain Monte Carlo (MCMC) techniques. Given a “target” density π , the key idea of MCMC is to build a Markov chain $\{X_i\}_{i \geq 0}$ of transition kernel $K(\cdot | \cdot)$ such that

$$\int K(x' | x) \pi(x) dx = \pi(x'), \quad (4)$$

i.e., if $X_{i-1} \sim \pi$ then any sample $X_i \sim K(\cdot | X_{i-1})$ is also distributed according to π . The target density π in (4) is known as the invariant (or stationary) distribution of the Markov chain. Under ergodicity conditions on the kernel $K(\cdot | \cdot)$, the samples $\{X_i\}_{i \geq 0}$ are distributed

according to π asymptotically (as $i \rightarrow \infty$) regardless of the value of initial state X_0 .

There are an infinity of kernels with invariant distribution π . However, the most frequently used are the Metropolis–Hastings kernels, first proposed by Metropolis et al. (1953), and then generalized by Hastings (1970). Green (1995) extended this to the case where $\mathcal{X}$ is a disjoint union of subspaces of different dimensions.

Given a candidate distribution $q(\cdot | \cdot)$ that is easy to sample from, the Metropolis–Hastings kernel can be constructed as follows: given X_{i-1}

(a) Sample a candidate $X^* \sim q(\cdot | X_{i-1})$ and compute

$$\alpha(X_{i-1}, X^*) = \frac{\pi(X^*) q(X_{i-1} | X^*)}{\pi(X_{i-1}) q(X^* | X_{i-1})}.$$

(b) Sample a uniform random variable U on $[0, 1]$. If $U \leq \alpha(X_{i-1}, X^*)$, then set $X_i = X^*$ otherwise set $X_i = X_{i-1}$.

It can be verified that the Markov chain $\{X_i\}_{i \geq 0}$ generated by the above kernel has invariant distribution π . Knowledge of the normalizing constant of π is not needed as it disappears in the acceptance ratio $\alpha(X_{i-1}, X^*)$. The major problem with such Markov chain techniques is that only samples from π are obtained as $i \rightarrow \infty$. Nevertheless, the Metropolis–Hastings algorithm and MCMC algorithms, in general, have been applied successfully in numerous applications. MCMC methods form the basis of global optimization algorithms such as simulated annealing (Van Laarhoven & Arts 1987). For a thorough treatment of the theory and applications of MCMC algorithms, the reader is referred to Robert & Casella, (1999).

Importance sampling (IS) is based on assigning weights (or importance) to samples generated from a candidate density q so as to approximate the target density π . Suppose that $\pi(x) = w(x) q(x)$, where q is a density that is easy to sample from. Then, given random samples $\{X^{(i)}\}_{i=1}^N$ distributed according to q , the expectation $I_\pi(\varphi)$ in Equation (1) can be estimated by the empirical average

$$\hat{I}_\pi(\varphi) = \frac{1}{N} \sum_{i=1}^N \varphi(X^{(i)}) w(X^{(i)}).$$

In other words, π is approximated by

$$\hat{\pi}_1(x) = \frac{1}{N} \sum_{i=1}^N w(X^{(i)}) \delta(x - X^{(i)}).$$

This strategy assumes full knowledge of π as $w(X^{(i)}) = \pi(X^{(i)})/q(X^{(i)})$ needs to be determined. When π is only specified upto normalizing constant,

write

$$\pi(x) = \frac{w(x)q(x)}{\int_{\mathcal{X}} w(x)q(x) dx}$$

and apply importance sampling to both numerator and denominator to yield the following approximation:

$$\hat{\pi}_2(x) = \sum_{i=1}^N \frac{w(X^{(i)})}{\sum_{j=1}^N w(X^{(j)})} \delta(x - X^{(i)}).$$

An approximate sample from π can be obtained by sampling from the discrete distributions $\hat{\pi}_1$ or $\hat{\pi}_2$.

Applications

The range of applications of Monte Carlo methods is vast. Listed below are some of the more well-known areas.

Integral equations: IS methods have been widely used to solve linear systems and integral equations appearing in particle transport problems. The basic idea is to give a probabilistic approximation of operators of the form $(I - H)^{-1} = \sum_{i=0}^{\infty} H^i$; see Sobol (1994) for details.

Computational physics and chemistry simulation: Monte Carlo methods are used in physics and chemistry to simulate from Ising models, simulate self-avoiding random walks, and compute the free energy, entropy, and chemical potential over systems; see, for example, Frenkel & Smith (1996).

Quantum physics: To compute the dominant eigenvalue and eigenvector of a positive operator, it is possible to use a stochastic version of the power method. This is often applied to the Schrödinger equation; see Melik-Alaverdian & Nightingale (1999) for a recent review.

Statistics: Performing inference in complex statistical models invariably requires sampling from high dimensional probability distributions. See Gilks et al. (1996) for applications of MCMC and Doucet et al. (2001) for applications of IS-type methods to such problems.

MORPHOGENESIS, BIOLOGICAL

One of the central problems in developmental biology is to understand how patterns and structures are laid down. From the initially almost homogeneous mass of dividing cells in an embryo emerges the vast range of pattern and structure observed in animals. For example, the skeleton is laid down during chondrogenesis when chondroblast cells condense into aggregates that lead eventually to bone formation. The skin forms many specialized structures such as hair, scales, feathers, and glands. Butterfly wings exhibit spectacular colors and patterns, and many animals develop dramatic coat patterns.

Although genes play a key role, genetics say nothing about the actual mechanisms that produce pattern and structure—the process known as morphogenesis—as an organism matures from embryo to adult. Tissue movement and rearrangement are the key features of almost all morphogenetic processes and arise as the result of complex mechanical, chemical, and electrical interactions. Despite the recent vast advances in molecular biology and genetics, little is understood of how these processes conspire to produce pattern and form. There is the danger of falling into the practices of the 19th century, when biology was steeped in the mode of classification and there was a tremendous amount of list-making activity. This was recognized by D'Arcy Thompson, in his classic work first published in 1917 (see Thompson (1992) for the abridged version). He was the first to develop theories for how certain forms arose, rather than simply cataloging different forms, as was the tradition at that time.

At the heart of a number of developmental phenomena is the process of convergence-extension, in which a tissue narrows along one axis while extending along another. This process represents the integration of local cellular behavior that produces forces to change the shape of the cell population. In fact, convergence-extension is essentially responsible for the transformation of the spherical egg into the elongated, bilaterally symmetric vertebrate body axis (Keller et al., 1992).

Cell fate and position within the developing embryo can be strongly influenced by environmental factors. Therefore, to investigate the process of morphogenesis, one must really address the issue of how the embryo organizes the complex spatiotemporal sequence of signalling cues necessary to develop structure in a controlled and coordinated manner. Structure can form through tissue movement and rearrangement. Theoretical studies in this area include the early purse-string model (Odell et al., 1981) for tissue folding in which, in response to a large deformation, cells were proposed to actively contract and, in doing so, cause a large deformation in neighboring cells which, in turn, also contract, setting up a propagating contraction wave which leads to tissue folding. This model was applied to a variety of developmental problems and provided the precursor to the mechanochemical theory of developmental patterning developed by Oster, Murray, and coworkers (for review, see Murray, 2003). This approach emphasized the link between tissue mechanics and chemical regulation and has been applied widely in both developmental biology and medicine.

Discrete-cell modeling approaches have subsequently been developed in which morphogenesis is hypothesized to occur via mechanical rearrangement of neighbors in an epithelial sheet, and computational finite elements have been developed to test various theoretical explanations for morphogenesis (Weliky et al., 1991; Davidson et al., 1995).

In all these models, individual cell movements within the tissue are determined by the balance of mechanical forces acting on the cell. Such models can exhibit tissue folding, thickening, invagination, exogastrulation, and intercalation, and have been shown to capture many of the key aspects of processes such as gastrulation, neural tube formation, and ventral furrow formation in *Drosophila*. Cells can also sort out depending on their type, and this has led to the theory of differential adhesion and energy minimization (Steinberg, 1970).

Models for tissue motion are not amenable to a mathematical analysis and tend to be highly computation based. However, models for how cells differentiate can be addressed mathematically. Broadly speaking, there are two classes of such models. In one class, the chemical pre-pattern models, it is hypothesized that a chemical signal is set up in some way and cells respond to this signal by differentiating. In the other class, the cell movement models, it is hypothesized that cells respond to mechanochemical cues and form aggregates. Cells in high density aggregates are then assumed to differentiate (see Murray, 2003, for details).

The fact that such models can lead to the generation of spontaneous order was first realized by Alan Turing (1952), who showed that a system of chemicals, stable in the absence of diffusion, could be driven unstable by

diffusion. He proposed that such a spatial distribution of chemicals (which he termed *morphogens*) could set up a pre-pattern to which cells could respond and differentiate accordingly. He was one of the first to postulate the existence of such chemicals, and morphogens have now been discovered. It is still not clear that morphogen patterns in biology are set up by the mechanism proposed by Turing, but Turing patterns have been found in chemistry (see Maini et al., 1997, for a review).

A variety of models based on different biology give rise to mathematical formulations in terms of coupled systems of highly nonlinear partial differential equations. The analysis of these models has, to date, yielded a number of common behaviors. This has led to the idea of using such models to determine developmental constraints. That is, independent of the underlying biology, such models predict that only certain patterns are selected at the expense of others and thus there is a limited variation. This has consequences for evolution. For example, application of mitotic inhibitors to developing limbs produces smaller limbs with reduced elements. Some of the resultant variants look very similar to the pattern of evolution in other species, suggesting that these species may be more closely related than previously thought (Oster et al., 1988). Moreover, the construction rules generated by a study of developmental constraints is another, perhaps more mechanistic, way of describing how different species are related other than the topological deformation approach of D'Arcy Thompson.

Other approaches to morphogenesis and pattern formation include cellular automata models, in which individual entities (cells, for example) behave according to a set of rules. Such models allow one to include much more biological detail and to investigate finer grain patterns than those possible in the continuum approaches discussed above (see, for example, Alt et al., 1997). However, to date they lack a detailed mathematical underpinning.

The recent spectacular advances in molecular genetics raise the issue of how we can combine the enormous amount of data now being generated at this level with the data available from the classical experiments at the cell and tissue level to provide a coherent theory for pattern formation and morphogenesis. This leads to the problem of modeling across a vast range of spatial and temporal scales. The mathematics for this has not yet been developed and is one of the challenges presently being addressed.

MULTIDIMENSIONAL SOLITONS

Although strict analogs of the Korteweg–de Vries soliton (exponentially localized solution with a specific relation between velocity and amplitude and particular scattering properties) have not been found in the multidimensional context, solvable equations with three or more independent variables exhibit a large variety of soliton-like solutions.

As with the Kadomtsev–Petviashvili equation, wide classes of exact explicit solutions have been constructed for other $(2+1)$ -dimensional nonlinear equations solvable by the inverse scattering method. We consider here two basic examples, the first being the Davey–Stewartson (DS) equation

$$iq_t + \frac{1}{2}(\sigma^2 q_{xx} + q_{yy}) + |q|^2 q - q\phi = 0, \\ \phi_{xx} - \sigma^2 \phi_{yy} = 2(|q|^2)_{xx}, \quad (1)$$

where $q(x, y, t)$ is a complex-valued function, ϕ is a real-valued function, and the parameter σ^2 takes two values $\sigma^2 = \pm 1$. The DS equation describes propagation of a two-dimensional long surface wave on water

of finite depth. In the one-dimensional limit $q_y = \phi_y = 0$, it reduces to the nonlinear Schrödinger equation.

The DS equation (1) has a Lax representation with the two-dimensional Dirac operator as the Lax operator, but it has quite different properties for $\sigma^2 = 1$ (DS-I equation) and for $\sigma^2 = -1$ (DS-II equation). In both cases, there are multi-soliton solutions which do not decay in certain directions on the x, y plane. Similar to the Kadomtsev–Petviashvili equation these solutions describe elastic scattering of line solitons that decay exponentially in the direction of propagation and do not decay in the orthogonal direction. The phase shift can be explicitly calculated.

In addition, the DS equation possesses novel classes of solutions. Thus, the DS-II equation has an infinite set of nonsingular exponential-algebraic solutions, the simplest of which looks like

$$q(x, y, t) = \frac{2v \exp \left[\lambda(x + iy) - \bar{\lambda}(x - iy) - i \left(\lambda^2 + \bar{\lambda}^2 \right) t \right]}{|x + iy + \mu - 2i\lambda t|^2 + |v|^2}, \quad (2)$$

where λ, μ , and v are arbitrary complex constants. It decays like $(x^2 + y^2)^{-1}$ as $x, y \rightarrow \infty$.

The DS-I equation also possesses solutions for which q decays exponentially in both space dimensions. The simplest of them is of the form

$$q(x, y, t) = \frac{4\rho\sqrt{\lambda}\mu \exp \left[\mu(x+y) + \lambda(x-y) + i(\mu^2 + \lambda^2)t \right]}{[1 + e^{2\mu(x+y)}][1 + e^{2\lambda(x-y)}] + |\rho|^2}, \quad (3)$$

where λ, μ are arbitrary real parameters and ρ is an arbitrary complex parameter. The function ϕ has the nontrivial boundary values as $x, y \rightarrow \infty$. Called dromions, such solutions exhibit not only a two-dimensional phase shift during interaction but also a change of the form. Basically, these solutions are driven by the boundary conditions on the function ϕ .

Our second example—the Ishimori equation—is of the form

$$S_t + S \times (S_{xx} + \sigma^2 S_{yy}) + \phi_x S_y + \phi_y S_x = 0, \\ \phi_{xx} - \sigma^2 \phi_{yy} + 2\sigma^2 S \cdot (S_x \times S_y) = 0, \quad (4)$$

where $S = (S_1, S_2, S_3)$ is a unit vector $S^2 = 1$, $\sigma^2 = \pm 1$, and ϕ is a scalar real-valued function. It represents an integrable $(2+1)$ -dimensional generalization of the Heisenberg Ferromagnet model equation $S = S \times S_{xx}$. An important feature of the Ishimori equation is that its solutions can be characterized by the topological invariant

$Q = (1/4\pi) \int \int dx dy \mathcal{S} \cdot (\mathcal{S}_x \times \mathcal{S}_y)$, which is conserved in time and takes integer values $N = 0, \pm 1, \pm 2, \dots$.

The Ishimori equation for both signs of σ^2 possesses multisoliton solutions that describe elastic scattering of line solitons. The Ishimori-I equation ($\sigma^2 = 1$) has a rich variety of the dromion-like solutions. An interesting feature is that the Ishimori-II equation ($\sigma^2 = -1$) consists of the existence of the topologically nontrivial multi-vortex solutions. The one-vortex solution looks like

$$S_1 + iS_2 = \frac{2\alpha\rho e^{-i\varphi}}{|\alpha|^2 + |\rho|^2}, \quad S_3 = \frac{|\alpha|^2 - |\rho|^2}{|\alpha|^2 + |\rho|^2}, \quad (5)$$

where $\rho e^{i\varphi} = x + iy - (x_0 + iy_0)$, α is an arbitrary complex constant, and $Q = 1$. An anti-vortex solution with $Q = -1$ is also given by (5) under the substitution $x + iy \rightarrow x - iy$, that is, $\varphi \rightarrow -\varphi$. General N -vortex solution has $Q = N$ and describes the time dynamics of the spin-vortices and spin-anti-vortices of the form (5) which exhibits no phase shifts. These solutions are all regular and rational functions on x and y ; in other words, they are lump solutions of the Ishimori-II equation.

Both the Davey–Stewartson and the Ishimori equations also possess infinite sets of exact solutions parameterized by finite number of arbitrary functions of one variable. As for the NLS equation and the Heisenberg ferromagnet equation, the DS equation and the Ishimori equation are related by the so-called gauge transformation.

Multidimensional nonlinear equations not solvable by the inverse scattering method do not possess multisoliton-like solutions. However, some of them, such as lumps, breathers, or spherical waves, have particular solutions which are similar to one soliton solution in some respects. Such solutions play roles in various nonlinear phenomena arising in classical and quantum field theories, in nonlinear theories of matter, and even in the theory of Jupiter's Great Red Spot.

MULTIFRACTAL ANALYSIS

A fractal is a geometrical shape that shows self-similarity, meaning that parts appear similar to the set as a whole (See **Fractals**). A multifractal is a fractal with a probability measure attributed to its geometrical support set. A typical multifractal can have different fractal dimensions in different parts of its support set, depending on the multifractal measure chosen. Typical examples of multifractals are attractors of nonlinear mappings, where the relevant probability measure is given by the invariant measure of the map. Often, quite a complicated structure is observed, and the invariant density may diverge at infinitely many points in the phase space with different exponents, that is, an entire spectrum of singularities is generated.

To statistically analyze this complex behavior, it is useful to evaluate the so-called Rényi dimensions D_q (Rényi, 1970). These are generalizations of the usual box dimensions (or capacity) that contain information not only on the topological structure of the fractal but on the probability measure as well. The simplest definition of the Rényi dimensions is as follows. Cover the fractal with small d -dimensional cubes ("boxes") of volume ε^d , where ε is the side length of the box and d is an integer dimension large enough to embed the fractal. For each such box i we consider the probability p_i that is associated with it:

$$p_i = \int_{i\text{th box}} \rho(x) dx. \quad (1)$$

Here $\rho(x)$ is the probability density considered. The Rényi dimensions are defined for any real parameter q as

$$D_q = \lim_{\varepsilon \rightarrow 0} \frac{1}{\varepsilon - \log \varepsilon} \frac{1}{q - 1} \log \sum_i p_i^q, \quad (2)$$

where the sum is over all i with $p_i \neq 0$. There are also more sophisticated definitions of the Rényi dimensions based on boxes of variable size (analogous to the definition of the Hausdorff dimension), see Beck & Schlögl (1993) for more details.

Generally, for a complicated multifractal (with lots of singularities of the probability density) the Rényi dimensions D_q depend on q , whereas for "simple" multifractals all D_q are the same and equal to the Hausdorff dimension. By changing the parameter q , one "scans" the structure of the multifractal. Large q values give more weight to large probabilities p_i , small q favor small probabilities p_i . Useful special cases of the Rényi dimensions are the box dimension (or capacity) D_0 (usually equal to the Hausdorff dimension, up to pathological cases), the information dimension D_1 (more precisely given by the limit $\lim_{q \rightarrow 1} D_q$), and the correlation dimension D_2 . The correlation dimension can be easily extracted from experimental time series using the Grassberger–Procaccia algorithm (Grassberger & Procaccia, 1983). It is also of relevance

Figure 1. Construction of a classical Cantor set with a multiplicative non-uniform measure.

for the estimation of typical period lengths that are generated due to computer roundoff errors in chaotic dynamical systems (Beck, 1989). Also important are the limit dimensions $D_{\pm\infty}$ obtained for $q \rightarrow \pm\infty$. They describe the scaling behavior of the invariant density in the region of the phase space where the measure is most concentrated (D_{∞}) and least concentrated ($D_{-\infty}$).

From the Rényi dimensions, one can proceed to $f(\alpha)$, the spectrum of local scaling exponents α of the measure, by a Legendre transformation. The basic idea is very similar to thermodynamics. In fact, many of the ideas of the multifractal formalism are related to early work by Sinai, Ruelle, and Bowen on the so-called “thermodynamic formalism” of dynamical systems (Ruelle, 1978). For multifractals, one can regard the function $\tau(q) = (q - 1)D_q$ as a kind of free energy, and q as a kind of inverse temperature (Tél, 1988; Beck & Schlögl, 1993). One then defines the variable α (the “internal energy”) by $\partial\tau/\partial q =: \alpha$ and proceeds to the $f(\alpha)$ spectrum (the “entropy”) by Legendre transformation:

$$f(\alpha) = q\alpha - \tau(q). \tag{3}$$

The advantage of the $f(\alpha)$ spectrum is that it has a kind of “physical meaning.” Roughly speaking, it is the fractal dimension of the subset of points for which the probability density scales with a local exponent α , that is, $p_i \sim \varepsilon^{\alpha_i}$ with $\alpha_i \in [\alpha, \alpha + d\alpha]$. Hence, this is a kind of statistical mechanics of local Hölder indices.

Let us consider a simple example of a multifractal, given by the classical Cantor set with a multiplicative (non-uniform) measure (Figure 1). The classical Cantor set is constructed by cutting the middle third out of the unit interval, then cutting out the middle third out of the remaining two intervals, and so on (See **Fractals**). In this way, at the k th construction step there are 2^k intervals of length $(\frac{1}{3})^k$. We now attribute a product measure to each of the intervals, according to the rule sketched in Figure 1, with $w_1 + w_2 = 1$ but $w_1 \neq w_2$. In the limit $k \rightarrow \infty$ we obtain a multifractal.

Figure 2. (a) Rényi dimensions and (b) $f(\alpha)$ spectrum of the Feigenbaum attractor.

Let us calculate the corresponding Rényi dimensions. We cover the multifractal with small intervals of size $\varepsilon_k = (\frac{1}{3})^k$. The number of boxes with probability $p_i = w_1^i w_2^{k-j}$ is

$$N_{k,j} = \binom{j}{k} = \frac{j!}{k!(k-j)!}. \tag{4}$$

Hence,

$$\sum_i p_i^q = \sum_{j=0}^k N_{k,j} w_1^{jq} w_2^{(k-j)q} = (w_1^q + w_2^q)^k \tag{5}$$

and for the Rényi dimensions, one obtains from definition (2)

$$D_q = \frac{\log(w_1^q + w_2^q)}{(1-q)\log 3}. \tag{6}$$

In particular, the box dimension D_0 is given by the value $D_0 = \log 2 / \log 3$, independent of w_1 and w_2 . The other dimensions depend on the probabilities w_j , for example, for the information dimension one obtains $D_1 = -(1/\log 3) \sum_{j=1}^2 w_j \log w_j$ by considering the limit $q \rightarrow 1$. The Legendre transform of (6) yields the $f(\alpha)$ spectrum.

Another interesting example is the attractor of the logistic map at the critical point of period doubling accumulation. Figure 2a shows the corresponding Rényi dimensions and Figure 2b the corresponding $f(\alpha)$ spectrum. Generally, the value of α where the function $f(\alpha)$ has its maximum is equal to the Hausdorff dimension of the attractor. The value of $f(\alpha)$ where the function has slope 1 is equal to the information dimension.

In practice, one often wants to evaluate the Rényi dimensions (or the $f(\alpha)$ spectrum) for a given time series (Kantz & Schreiber, 1997) of experimental data without explicitly knowing the underlying dynamics or the invariant measure. Here, various interesting methods are known (Grassberger–Procaccia algorithm (Grassberger & Procaccia, 1983), wavelet analysis (Arneodo et al., 1995), etc.). These algorithms can be implemented without explicitly knowing the underlying dynamics. The wavelet transform of an

experimental signal $s(x)$ is defined as

$$W_\Psi(x_0, a) = \frac{1}{a} \int_{-\infty}^{+\infty} \Psi^* \left(\frac{x - x_0}{a} \right) s(x) dx, \quad (7)$$

(* indicates complex conjugate), where the analyzing wavelet Ψ is some localized function, often chosen to be the N th derivative of a Gaussian function. For small a , the wavelet transform extracts local Hölder exponents from the signal s , and q th moments of W_Ψ can then be used to define suitable partition functions which yield the Rényi dimensions.

MULTIFRACTAL MEASURE

See **Dimensions**

MULTIPLE SCALE ANALYSIS

For a number of problems involving differential equations, we know methods that can provide exact solutions. However, the vast majority of modeling problems have a complexity that forbids finding an exact solution by paper and pencil. It may appear that the only way forward is to use numerical analysis. However, this is not necessarily the case since we can resort to finding good approximate solutions by various methods or strategies. In applications we usually encounter systems with dissipation and energy input, where neglecting these energy exchange terms leads to an exact solvable problem. We can then employ a strategy based on the assumption that the exact solution of the unperturbed problem is only modified slightly by adding the perturbation terms and hope that the difference between the two solutions can be estimated

sufficiently accurately by assuming the perturbation is weak (Nayfeh, 1973, 1981, 2000).

Let us illustrate such a strategy by considering the damped harmonic oscillator. Denoting the displacement from equilibrium by $x(t)$ at time t , the dynamical equation reads

$$\ddot{x} + x = -\varepsilon \dot{x}. \quad (1)$$

A dot above the dependent variable $x(t)$ denotes differentiation with respect to time t . The damping parameter ε we shall vary, and accordingly it is natural to include ε in the argument list of $x = x(t; \varepsilon)$. The unperturbed oscillator corresponds to $\varepsilon = 0$, and using the initial conditions $x(0) = 1$ and $\dot{x}(0) = 0$, the solution of the unperturbed harmonic oscillator reads

$$x(t; 0) = x_0(t) = A \cos(t), \quad (2)$$

where the amplitude A equals unity. For the same initial conditions, the damped harmonic oscillator (1) with $\varepsilon \neq 0$ possesses the more complicated solution

$$x(t; \varepsilon) = e^{-\varepsilon t/2} \left[\cos \left(t \sqrt{1 - \varepsilon^2/4} \right) + \frac{\varepsilon/2}{\sqrt{1 - \varepsilon^2/4}} \sin \left(t \sqrt{1 - \varepsilon^2/4} \right) \right]. \quad (3)$$

The exact solution has features which can be used as a guide for developing a systematic way of finding an approximate solution assuming small damping, that is, $|\varepsilon| \ll 1$.

Without surprise, we recognize that the damping leads to a decreasing amplitude as time progresses but on a slow time scale of order $O(\varepsilon)$. Another result of the damping effect is an $O(\varepsilon^2)$ change of the frequency, which is $\omega = \sqrt{1 - \varepsilon^2/4} \approx 1 - \varepsilon^2/8$. The damping slows down the oscillation, and accordingly the period increases, hence the frequency decreases. Suitable corrections are therefore to allow for a slow variation of the amplitude A and for an even smaller correction of the frequency. In general terms, this implies that we need to let $x(t; \varepsilon)$ depend on the slower time scales εt and $\varepsilon^2 t$. We can formalize this by introducing (Nayfeh, 1981)

$$T_0 = t, \quad T_1 = \varepsilon t, \quad T_2 = \varepsilon^2 t, \\ x(t) = x(T_0, T_1, T_2). \quad (4)$$

Thus, the time derivatives expand as

$$\frac{d}{dt} = \frac{\partial}{\partial T_0} + \varepsilon \frac{\partial}{\partial T_1} + \varepsilon^2 \frac{\partial}{\partial T_2} + O(\varepsilon^3), \quad (5) \\ \frac{d^2}{dt^2} = \frac{\partial^2}{\partial T_0^2} + 2\varepsilon \frac{\partial^2}{\partial T_0 \partial T_1} + \varepsilon^2 \left(\frac{\partial^2}{\partial T_1^2} + 2 \frac{\partial^2}{\partial T_0 \partial T_2} \right) + O(\varepsilon^3), \quad (6)$$

by invoking the chain rule for partial derivatives. The idea is to introduce slowly time-varying coefficients by regarding the new scaling variables in (4) as

independent variables. This is a somewhat mysterious trick, and it is not easy to understand why it works, since the scaling variables are all proportional to time, but it does. In perturbation theory, we often rely on such experience and tricks.

After having introduced the scaling into our original problem, we can add further corrections to the unperturbed solution by introducing a Taylor expansion around $\varepsilon = 0$ with respect to the perturbation parameter ε

$$x(\mathbf{T}; \varepsilon) = x_0(\mathbf{T}) + x_1(\mathbf{T})\varepsilon + x_2(\mathbf{T})\varepsilon^2 + O(\varepsilon^3), \quad (7)$$

where

$$\mathbf{T} = (T_0, T_1, T_2) \quad \text{and} \quad x_n(\mathbf{T}) = \frac{1}{n!} \frac{\partial^n x(\mathbf{T}; 0)}{\partial \varepsilon^n}.$$

Inserting the Taylor expansion into Equation (1) results in a polynomial in ε which equals zero. The coefficient of ε^n is a differential operator working on x_n , and as all these coefficients must vanish, we have a differential equation for each x_n , which normally is simple enough that it can be solved analytically, at least for the first few equations. Inserting the Taylor expansion into Equation (1) and ordering according to powers of ε we obtain

$$x_0, T_0 T_0 + x_0 = 0, \quad (8)$$

$$x_1, T_0 T_0 + x_1 = -x_0, T_0 - 2x_0, T_0 T_1, \quad (9)$$

$$x_2, T_0 T_0 + x_2 = -x_1, T_0 - 2x_1, T_0 T_1 - x_0, T_1 - x_0, T_1 T_1 - 2x_0, T_0 T_2. \quad (10)$$

Subscript T_0 means a partial derivative with respect to T_0 and similarly for the analogous subscripts. The solution of the first equation reads

$$x_0 = A(T_1, T_2)e^{iT_0} + B(T_1, T_2)e^{-iT_0}. \quad (11)$$

The fact that A and B depend on T_1 and T_2 expresses the slow variation of these parameters with time. The solution of the equation for x_1 can now be found by inserting x_0 from (11) into the right-hand side of Equation (9),

$$x_1, T_0 T_0 + x_1 = -i(A + 2A_{T_1})e^{iT_0} + i(B + 2B_{T_1})e^{-iT_0}. \quad (12)$$

Terms proportional to the exponentials $e^{\pm iT_0}$ are resonant forcing terms, leading to a growth of x_1 proportional to time t . When t is of order $1/\varepsilon$, the term $\varepsilon x_1(t)$ has become of order unity, and our analysis breaks down. Such terms are called secular terms. In order to get a uniform and valid expansion, we need to avoid secular terms. However, due to the dependence on T_1 of A and B , we can demand that coefficients proportional to $e^{\pm iT_0}$ vanish thereby providing simple differential equations for determining A

$$A + 2A_{T_1} = 0 \quad \Rightarrow \quad A(T_1, T_2) = A_1(T_2)e^{-T_1/2}, \quad (13)$$

and similarly for B . Equation (12) now possesses the solution $x_1 = 0$. We can proceed by solving the $O(\varepsilon^2)$ equation (10) and invoke the initial conditions $x(0) = 1$ and $\dot{x}(0) = 0$. After rather straightforward calculations, we obtain the approximate solution (Scott, 2003)

$$x(t) = e^{-\varepsilon t/2} \cos[(1 - \varepsilon^2/8)t] + \frac{\varepsilon}{2} e^{-\varepsilon t/2} \times \sin[(1 - \varepsilon^2/8)t] + O(\varepsilon^3) \quad (14)$$

in agreement with the exact solution to the desired order in ε . Carrying out the analysis to order $O(\varepsilon^n)$ requires introduction of scaled variables up to the same order for the perturbation analysis to be consistent. The above approach is called the method of multiple scales, and it has been applied to many nonlinear ordinary differential equations as well as perturbed soliton equations (McLaughlin & Scott, 1978; Scott, 2003), including derivations of nonlinear partial differential equations (Dodd, 1984). An interesting extension of the method to nonlinear difference equations is presented in Broomhead & Rowlands (1983).

MULTIPLEX NEURON

Under the view that dominated neuroscience around the middle of the 20th century, neural information processing involves three components (McCulloch & Pitts, 1943). First, incoming signals from chemical synapses on the dendritic trees are gathered as a linear, weighted sum of input signals. Second, this sum is compared with a threshold level at the base (initial segment) of the outgoing axonal tree. Finally, if the threshold level is exceeded, an active (all-or-nothing) nerve impulse is launched on the axonal tree, which propagates outward without failure to all of

Figure 1. (a) Abrupt widening of a nerve fiber. (b) Branching region.

the distal (distant) twigs of the tree, providing inputs to other neurons or to muscle cells. A simplifying feature of this “McCulloch–Pitts model” is that the incoming dynamics are entirely linear, governed by inhomogeneous diffusion processes on the dendritic trees.

Before the end of the 1960s, there was no compelling evidence to abandon this simple view of dendritic dynamics, and two reasons for clinging to it. If all-or-nothing propagation is supposed to occur on dendrites, then the entire tree might be expected to ignite, preventing the dendrites from integrating incoming information. Additionally, the assumption of linear dendritic dynamics helps the theorist to sort out various causal influences, somewhat easing the difficulties of analyzing neural systems (Scott, 2002).

By the 1970s, three types of evidence began to indicate that dendritic and axonal dynamics are more complex. First, impulse blockage was experimentally observed in the optic nerves of cats, implying that impulses (spikes) can be extinguished at axonal branchings (Chung et al., 1970). Second, experimental studies showed that spikes do indeed propagate on the dendritic trees of some vertebrate neurons (Llinás & Nicholson, 1971). Third, numerical studies by Boris Khodorov and his colleagues in the Soviet Union on realistic models of nerve fibers confirmed that the propagation of active nerve impulses can indeed be blocked at changes in fiber geometry such as the abrupt widening and branching regions shown in Figure 1 (Khodorov, 1974).

These considerations suggested the concept of a “multiplex neuron,” where the term (borrowed from communication engineering) implies the ability to handle two or more messages at the same time. As defined by Steven Waxman, a multiplex neuron has the following salient properties (Waxman, 1972).

- Impulse blockage at the branching regions of dendritic trees allows the possibility of Boolean logic, similar to the elementary operations of a digital computer. If the geometry of the branch is such that an impulse incoming on either daughter branch (one “or” the other) is able to ignite an outgoing impulse on the parent branch, this would be OR logic. If, on the other hand, coincident impulses on both incoming branches (one “and” the other) are required to ignite an outgoing impulse, it would be an example of AND logic. Thus the computational

Membrane model	Transmission	Blockage
H–H	5.5084	5.5126
M–L	2.2521	2.2563

Table 1. Widening ratios at which isolated impulses transmit and become blocked under Hodgkin–Huxley (H–H) and Morris–Lecar (M–L) membrane models (Altenberger et al., 2001).

nature of a branching region may depend upon details of its geometry.

- Impulse blockage at branching regions of the axonal tree allows an impulse code transformation under which a time code on the trunk of the tree is transformed to space-time codes at the distal branches (twigs) of the tree.

Seminal Soviet studies of the propagation of impulses through the abrupt widening shown in Figure 1(a) showed that blockage of an isolated Hodgkin–Huxley impulse (Hodgkin & Huxley, 1952) (which corresponds to the dynamics of a squid giant axon) was to be expected at a widening ratio (d_2/d_1) greater than about 5.5. As indicated in Table 1, recent numerical studies by Altenberger et al. (2001) have confirmed the early Soviet results for the Hodgkin–Huxley model and extended them to the Morris–Lecar model (which represents dynamics on barnacle giant muscle fibers and more closely models the calcium dominated dynamics of typical dendritic fibers) (Morris & Lecar, 1981).

Although abrupt widenings of real nerve fibers are not observed, numerical blocking conditions in Figure 1(a) can be related to the corresponding blocking conditions in Figure 1(b) through the concept of a “geometric ratio” (GR) (Goldstein & Rall, 1974). Assuming a discontinuity with several outgoing fibers (of diameters d_{out}) and on which an impulse is incoming on a single fiber of diameter d_{in} , the GR is defined as $\sum d_{out}^{3/2}/d_{in}^{3/2}$, where the “3/2 powers” enter because branching currents divide in proportion to the characteristic admittance of the outgoing fibers (Scott, 2002).

Assuming the Morris–Lecar (M–L) model and an incoming impulse on daughter branch # 1 in the branch of Figure 1(b), the AND condition is

$$\frac{d_2^{3/2} + d_3^{3/2}}{d_1^{3/2}} > 2.2563^{3/2} = 3.389, \tag{1}$$

requiring coincident inputs on both incoming branches (# 1 and # 2) for an impulse on the outgoing branch (# 3) to ignite. If this geometric inequality is not satisfied, the branch executes OR logic, in which incoming impulse either on daughter # 1 or on daughter # 2 is able to ignite an outgoing impulse on the parent branch (# 3).

Cell type	GR range
Purkinje	2.3–3.5
Stellate	2.4–3.5
Granule	2.3–4.8
Motoneuron	2.6–3.4
Pyramidal (apical)	2.5–3.4
Pyramidal (basal)	2.4–3.1

Table 2. The GR range for some typical dendrites (Scott, 2002).

Noting the GR values for typical dendritic trees given in Table 2 and considering the several ways in which critical GRs might be lowered in real neurons (changes in ionic concentrations, variations in channel membrane density, incomplete impulse recovery from previous interactions, and so on), it seems prudent to anticipate that dendritic trees can execute logical operations on the incoming (synaptic) codes, as is assumed in the multiplex neuron model (Stuart et al., 1999).

MULTIPLICATIVE NOISE

See **Stochastic processes**

MULTIPLICATIVE PROCESSES

Random processes involving accumulation and/or reduction occur widely in nature and in mathematics. At the most basic level, the laws of accumulation (and reduction) may be represented either as the result of arithmetic summation (and differencing) or as the result of multiplications. The latter such processes are the subject of this article.

Any attempt to embody all multiplicative random processes in a single mathematical definition would be futile. However, it is possible to provide large classes of examples for which rich mathematical theories and applications are possible.

The “law of proportionate effect” provides the basis for the evolution of multiplicative stochastic processes $M_0, M_1, \dots$, found, for example, in materials science, biology, economics, and finance, in terms of the proportionate changes $r_{n+1} = \Delta M_n / M_n \equiv (M_{n+1} - M_n) / M_n, n = 0, 1, 2, \dots$. In finance, M_n may be the value of a unit of stock at the n th period of time when subjected to the hypothesis that the yields $r_1, r_2, \dots$ are stationary and independent from time period to period. In materials science, on the other hand, M_n may represent the strength of a material after n repeated independent random impacts $R_1 = 1 + r_1, R_2 = 1 + r_2, \dots$. Similarly, M_n may represent the size of a biological population whose subsequent growth is in (random) proportions $r_1, r_2, \dots$ to the amount of substance available. The law of proportionate effect is a widely observed statistical law according to which the sequence of proportionate changes $r_{n+1} = \Delta M_n / M_n, n = 0, 1, 2, \dots$, is a sequence of independent and identically distributed (iid) random variables. Equivalently, one may iterate this law to obtain the so-called geometric random walk model:

$$M_n = M_0 \prod_{k=1}^n R_k, \quad k = 1, 2, \dots, \tag{1}$$

where

$$R_k = 1 + r_k, \quad k = 1, 2, \dots. \tag{2}$$

The special case in which R_n has two possible values, corresponding to upward and downward price movements, yields the binomial tree model for stock prices popular in the modern mathematical finance literature (Föllmer & Schied, 2002).

A more general notion of “multiplicative processes”, whose origins may be traced back to early 19th century genetics, occurs by consideration of a somewhat finer scale growth rule. In particular, changes to the process occur as M_{n+1} evolves from a previous random number

M_n of constituent members, each of which individually contributes its own growth and decay amounts (Y) to the whole in successive time steps. This more general stochastic law of evolution may be precisely expressed by the following iteration scheme: If $M_n = 0$ then define $M_{n+1} = 0$, else if $M_n > 0$ define

$$M_{n+1} = \sum_{k=1}^{M_n} Y_{n+1,k} \quad n = 0, 1, \dots, \quad (3)$$

where M_0 is a nonnegative integer valued (counting) random variable representing an initial size, and for each $n \geq 0$, the random variables $Y_{n+1,1}, Y_{n+1,2}, \dots, Y_{n+1,M_n}$ are nonnegative integer valued, representing the respective numbers of offspring of each of the M_n elements composing the n th generation.

Two special cases may be noted. In the case that the $Y_{n+1,k} \equiv R_{n+1}$, $k \geq 1$, are the same for each k of the n th generation, but are independent and identically distributed (iid) from generation to generation n , Equation (3) is the law of proportionate effect. On the other hand, if for each n , the offspring sizes $Y_{n+1,1}, Y_{n+1,2}, \dots$ are iid and independent of M_n , then Equation (3) defines the classical Bieneymé-Galton-Watson branching process (BGW) introduced in the early 19th century as a model for analyzing the survival of family names (Kendall, 1975).

A next generation of multiplicative processes arises out of these models by a still finer coding of the underlying phenomena. For simplicity, consider the BGW branching process and assume a single progenitor $M_0 = 1$. Then one may code the successive offspring as a random tree as follows: The single progenitor is coded by the empty sequence $\emptyset$. Its respective $Y_{1,1}$ offspring are coded (labeled) as $\langle 1 \rangle, \dots, \langle Y_{1,1} \rangle$. The $Y_{2,k}$ next generation offspring of $\langle k \rangle$ can be coded as $\langle k1 \rangle, \langle k2 \rangle, \dots, \langle kY_{2,k} \rangle$, and so on. In this way, the successive generations may be represented as a sequence of random family trees

$$\begin{aligned} \tau_0 &= \{\emptyset\}, \quad \tau_1 = \{\emptyset, \langle 1 \rangle, \dots, \langle Y_{1,1} \rangle\} \\ &\equiv \tau_0 \cup \{\langle 1 \rangle, \dots, \langle Y_{1,1} \rangle\}, \\ \tau_2 &= \tau_1 \cup \{\langle 11 \rangle, \dots, \langle 1Y_{2,1} \rangle, \dots, \\ &\quad \langle Y_{1,1}1 \rangle, \dots, \langle Y_{1,1}Y_{2,Y_{1,1}} \rangle, \dots \end{aligned}$$

This, in fact, suggests an alternative description of the BGW process as a probability distribution P on a (metric) space of tree graphs. Specifically, let $\mathcal{T}$ be the space of (possibly infinite) labeled tree graphs rooted at $\emptyset$. As above, an element τ of $\mathcal{T}$ may be coded as a set of finite sequences of positive integers $\langle i_1, i_2, \dots, i_n \rangle \in \tau$ such that:

- (i) The root $\emptyset \in \tau$ is coded as the empty sequence.
- (ii) If $\langle i_1, \dots, i_k \rangle \in \tau$ then $\langle i_1, \dots, i_j \rangle \in \tau \quad \forall 1 \leq j \leq k$.
- (iii) If $\langle i_1, i_2, \dots, i_n \rangle \in \tau$ then $\langle i_1, \dots, i_{n-1}, j \rangle \in \tau \quad \forall 1 \leq j \leq i_n$.

Neighboring vertices are those of the form $\langle i_1, \dots, i_n \rangle$ and $\langle i_1, \dots, i_{n-1} \rangle$. The last condition (iii) specifies a left to right labeling of vertices, and (ii) connects all paths to the root via neighboring vertices without cycles. The space $\mathcal{T}$ of such trees may be viewed as a metric space with metric defined by $\rho(\tau, \gamma) = (\sup\{n+1 : \gamma|_n = \tau|_n\})^{-1}$, and $\tau|_n = \{\langle i_1, \dots, i_k \rangle \in \tau : k \leq n\}$ is the truncation of τ to its n generations. This metric is complete and the countable dense subset $\mathcal{T}_0$ of finite labeled tree graphs rooted at $\emptyset$ makes $\mathcal{T}$ a separable metric space as well.

The BGW model may now be viewed as a probability distribution on the space $\mathcal{T}$, wherein the probability assigned to the ball B of radius $1/N$ centered at τ is given by

$$P(B) = \sum_{v \in \tau|N} p(\omega(\tau; v)), \quad (4)$$

where $p(j) = P(Y = j)$, $j = 0, 1, 2, \dots$ is a prescribed offspring probability distribution, and $\omega(\tau; v) = \max\{j : \langle v1 \rangle, \dots, \langle vj \rangle \in \tau\}$ counts the number of offspring of the vertex v in the tree τ .

A number of naturally occurring geophysical and biological structures admit natural tree codings, for example, river networks, lightning discharge patterns, and arterial and neural networks in human organs. Probabilistic models correspond to probability distributions on $\mathcal{T}$, leading to further generalizations of multiplicatively branching models; for example, see Barndorff-Nielsen et al. (1998) and references therein.

Random multiplicative cascade models provide another class of multiplicative processes of interest for their intermittency, extreme variability, and multiscaling structure in applications to phenomena ranging from fluid turbulence and spatial oceanic rainfall distributions to internet packet data on the world wide web (Barndorff-Nielsen et al., 1998; Gilbert et al., 1999; Jouault et al., 2000). The origins of this class of models trace back to classic work of Lewis Fry Richardson (1926), Andrei N. Kolmogorov (1962), and A.M. Yaglom (1966) in statistical turbulence theory. A rich geometrical and scaling perspective was subsequently advanced by Benoit Mandelbrot, and a more complete mathematical treatment was initiated by J.-P. Kahane and Jacques Peyrière (Kahane, 1985).

In the context of turbulence, one imagines introducing energy into the fluid by a large-scale stirring motion, whereby smaller-scale eddies split off and dissipate energy in random proportions R to those available. These eddies in turn split off smaller-scale eddies, and so on. In the simplest mathematical formulation, one considers random measures $M_n(\Delta)$ on the one-dimensional unit interval $[0, 1]$ having a piecewise constant density

$\rho_n(x)$ defined by a constant value over a dyadic subinterval

$$\Delta_n(j_1, \dots, j_n) = \left[\sum_{k=1}^n j_k 2^{-k}, \sum_{k=1}^n j_k 2^{-k} + 2^{-n} \right],$$
$$j_k \in \{0, 1\}, k \geq 1 \tag{5}$$

with constant value

$$\rho_n(x) = \prod_{k=1}^n R_{(j_1 j_2 \dots j_k)}, \quad \forall x \in \Delta_n(j_1, j_2, \dots, j_k), \tag{6}$$

where the random factors $R_v, v = (j_1 j_2 \dots j_k)$, are iid nonnegative mean one random variables indexed by the vertices of the binary tree. The mean one condition provides conservation of the mass of M_n on average, where for any Borel subset G

$$M_n(G) = \int_G \rho_n(x) \, dx. \tag{7}$$

The multiplicative cascade M_∞ is the random measure obtained by passing to the fine scale limit as $n \rightarrow \infty$.

The random cascade is defined by the branching number b ($= 2$ in this exposition), and the random factors R_v , referred to as cascade generators. Kolmogorov’s “log-normal hypothesis” refers to a choice of lognormal distribution for R . Tests of this hypothesis and physical arguments for alternative laws present significant challenges for modern statistical turbulence theory (e.g., She & Waymire, 1995; Jouault et al., 2000). On the mathematical side, the special choice of symmetrically distributed 0–2 valued generators yields the BGW process with binomial offspring distribution $p(j) = \binom{2}{j} \frac{1}{4}$, $j = 0, 1, 2$, for the total masses $M_n([0, 1])$, $n = 1, 2, \dots$. Refinements for which the branching number b may be viewed as a random parameter are given in Burd & Waymire (2000), and as a continuous parameter in Barral & Mandelbrot (2002).

Branching random walk models of the type illustrated by this next application may also be viewed within the framework of random multiplicative cascades. An explicit representation of the Fourier transform of classes of solutions to 3-d incompressible Navier–Stokes equations

$$\frac{\partial u}{\partial t} + u \cdot \nabla u = \nu \Delta u - \nabla p + g, \quad \nabla \cdot u = 0, \tag{8}$$

in the form of an expected value of a certain product of initial and forcing data evaluated at the nodes of a branching random walk was recently uncovered (LeJan & Sznitman, 1997). While probability models have long enjoyed important connections to partial differential equations, most notable being the heat equation and reaction-diffusion equations, this ranks among the most striking recent connections between multiplicative cascades and nonlinear equations of fluid

Figure 1. A sample tree graph for the Burgers equation.

motion. For a simple illustration of ideas made possible by refinements of the theory developed in Bhattacharya et al. (2003), consider the one-dimensional Burgers equation

$$u_t + uu_x = \nu u_{xx}, \quad u(0, x) = u_0(x). \tag{9}$$

Spatial Fourier transform will be denoted by $\hat{u}$. For simplicity of exposition, assume $\hat{u}_0(\xi) = 0$ for $\xi \leq 0$; that is, the initial data belongs to a Hardy function space. Taking spatial Fourier transforms one obtains, with the aid of an exponential integrating factor and $\xi > 0$ and writing

$$\lambda(\xi) = \nu \xi^2, \quad m = -\frac{i}{\nu}, \tag{10}$$

the result

$$\hat{u}(t, \xi) = e^{-\lambda(\xi)t} \hat{u}_0(\xi) + \frac{m}{2} \int_0^t \lambda(\xi) e^{-\lambda(\xi)s} \frac{1}{\xi} \times \int_0^\xi \hat{u}(t-s, \eta) \hat{u}(t-s, \xi-\eta) \, d\eta. \tag{11}$$

Expressed in this form, Equation (11) takes on a probabilistic meaning. In particular, this is a recursive equation for the expected values of a multiplicative stochastic process initiated at $\xi_0 = \xi$. The first term on the right-hand side $e^{-\lambda(\xi)t} \hat{u}_0(\xi)$ is the product of the initial data $\hat{u}_0(\xi)$ times the probability $e^{-\lambda(\xi)t}$ that an “exponentially distributed clock” with parameter $\lambda(\xi)$ rings after time t . The second integral term is an expected value in the complementary event of probability density $\lambda(\xi) e^{-\lambda(\xi)s}$, that the clock rings at time s prior to t . Given that the clock rings at a time s prior to t , a product is formed with the factor $m(\xi)$ and a random selection of a pair of new “offspring” wave numbers (or Fourier frequencies) $\eta, \xi - \eta$ from the interval $[0, \xi]$ with (uniform) probability density $1/\xi$ to complete the recursion over the remaining time $t - s$. That is to say, the unique solution (in the appropriate

function space) is furnished by the expected value

$$\hat{u}(t, \xi) = EX(t, \xi), \quad \xi > 0, \quad (12)$$

for a multiplicative cascade $X(t, \xi)$ defined by the following stochastic recursion in Fourier wave number space (see Figure 1): A particle of type $\xi_0 = \xi$ waits for an exponentially distributed time S_0 with mean $1/\lambda(\xi) = \frac{1}{v\xi^2}$. If $S_0 > t$ then a value $\hat{u}_0(\xi)$ is assigned to the initial vertex $\emptyset$ and the process terminates. On the other hand, if $S_0 \leq t$ then an independent coin flip is made. If the outcome is a tail then the particle dies and a value 0 is assigned, but if a head occurs then the particle branches into two particles $\langle 1 \rangle$, $\langle 2 \rangle$ of respective types $\xi_{(1)} = \eta$ and $\xi_{(2)} = \xi - \eta$ selected according to the uniform distribution on $[0, \xi]$. Two independent exponential clocks $S_{(1)}$, $S_{(2)}$, with respective parameters $\lambda(\xi_{(1)})$, $\lambda(\xi_{(2)})$, are set, and the process is repeated independently from each of these two given types for the termination time t reduced to $t - S_0$. The multiplicative cascade $X(t, \xi)$ is, up to a (random) power of $m \equiv -\sqrt{-1}/v$, a product of the assigned values of $\hat{u}_0$ at the selected frequencies; for example, for the sample realization depicted in Figure 1, one has

$$X(t, \xi) = m^2 \cdot \hat{u}_0(\xi_{(11)}) \cdot \hat{u}_0(\xi_{(12)}) \cdot \hat{u}_0(\xi_{(2)}) \cdot 0. \quad (13)$$

In particular, the premature death of $\langle 2 \rangle$ means that this particular sample realization will not contribute a positive value to the mathematical expectation in (12).

By presenting these models as a progression of modifications and extensions built on simpler structures, some sense of a mathematical theory begins to emerge, a large part of which directly rests on martingale theory. For example, for the BGW model one may observe, denoting the mean offspring number by μ , assumed positive and finite, that M_n/μ^n , $n = 1, 2, \dots$, is a martingale. Similarly, for each fixed Borel set G , the cascade measure $M_n(G)$, as a function of (logarithmic) scale $n = 1, 2, \dots$, is a martingale. The latter property led Kahane to still further natural generalizations of widespread significance (Kahane, 1985). Such deep mathematical structure has made it possible to precisely analyze many of the singularities, intermittencies, and other critical phenomena associated with these models, as well as to provide precise statistical error bars required for scientifically sound empirical estimations and tests of hypothesis for multiplicative cascades. On the other hand, the overall theory is in its relative infancy and many questions of practical importance remain open (Ossiander & Waymire, 2000). Needless to say, the relationship with the incompressible Navier–Stokes equations provides a link to one of the most outstanding mathematical problems of our times.

MULTISOLITON PERTURBATION THEORY

Solitons appear as robust solutions of several important nonlinear partial differential equations and difference-differential equations, including the Korteweg–de Vries (KdV), nonlinear Schrödinger (NLS), and sine-Gordon (SG) equations and the Toda lattice (TL). It is a remarkable feature of these and other equations, integrable by means of the inverse scattering transform (IST), that one can find exact multisoliton solutions. Among other phenomena, multisoliton solutions describe collisions among several solitons and bound states of solitons (breathers).

Considering systems that conserve energy but lack integrability, multisoliton solutions, and breathers may be only approximate, their dynamics accompanied by emission of radiation. As a result, two colliding solitons may merge into a breather, and the energy of a breather gradually decreases until it completely decays.

The situation is yet more different from that in integrable models if the system is dissipative. The dissipative loss of energy may be offset by an external field (driving force). A well-known example is the damped-driven SG equation

$$\phi_{tt} - \phi_{xx} + \sin \phi = -\alpha \phi_t - \gamma, \tag{1}$$

which models magnetic flux propagation on a long Josephson junction (LJJ) (McLaughlin & Scott, 1978). In this equation, $\partial \phi / \partial x$ is the local magnetic field, α is a coefficient of dissipation, and γ is a bias-current density, which is the driving force. In the absence of perturbations ($\alpha = \gamma = 0$), (1) is the SG equation, whose fundamental soliton solution is the kink (it represents a magnetic-flux quantum, or fluxon, in LJJ),

$$\phi_k = 4 \tan^{-1} \left[\exp \left(\sigma \frac{x - \xi(t)}{\sqrt{1 - c^2}} \right) \right]. \tag{2}$$

Here, $\sigma = \pm 1$, c , and $\xi(t)$ are, respectively, the polarity, velocity, and central coordinate of the kink (or fluxon). An exact breather solution to the unperturbed SG equation is

$$\phi_{br} = 4 \tan^{-1} \left[\frac{\sin(t \cos \mu)}{\cosh(x \sin \mu)} \tan \mu \right], \tag{3}$$

where the amplitude μ takes values $0 < \mu < \pi/2$. In the limiting case $\mu \rightarrow \pi/2$, (3) becomes a solution describing collision between two kinks with opposite polarities.

In the presence of perturbations, Equation (1) still has kink-like solutions, but the kink’s steady-state velocity (c_0) is no longer arbitrary. It is determined by the condition that the power input from a constant driving force (γ) is in balance with the dissipation induced by the loss term, which yields

$$c_0 = \frac{\sigma \pi \gamma}{\sqrt{(\pi \gamma)^2 + 16 \alpha^2}}. \tag{4}$$

According to Equation (4), kinks with opposite polarities move in opposite directions; hence, they may collide.

If an ac driving force is applied to the system [e.g., $\gamma = \gamma_0 \cos(\omega t)$ in (1)], it may compensate the loss and support the breather whose frequency $\cos \mu$ is in resonance with the driving frequency ω . If γ in (1) is a random function of time, and α is small enough, the random force can split the breather into a free kink-antikink ($k\bar{k}$) pair.

In the general case, basic effects produced by perturbations acting on two- or multi-soliton configurations may be classified as follows. Interaction between two solitons in the presence of conservative perturbations gives rise to emission of radiation, which appears at order ε^2 , where ε is the strength of the perturbation. Adiabatic effects (those that neglect radiation) may be generated by conservative perturbations in a three-soliton system at order ε , in the form of energy exchange between colliding solitons (this may also occur in a two-soliton system if the conservative perturbation is not spatially uniform—for instance, if it is created by a local defect). In the case of dissipative perturbations, nontrivial effects are possible at order ε for two solitons, typical examples being fusion of a $k\bar{k}$ pair into a breather or, inversely, breakup of a breather into a pair due to its collision with another kink.

If the model is a perturbed version of an integrable one, multi-soliton processes similar to those outlined above can be investigated by means of perturbation theory (PT), a powerful version of which is based on a perturbed variant of IST (Kaup & Newell, 1978). As in the integrable case, the initial configuration is mapped into scattering data of the corresponding scattering problem, but the time evolution of the scattering data is no longer trivial, discrete eigenvalues being no more

time-independent. Using a perturbative expansion, it is possible to derive ordinary differential equations (ODEs) for slow variations of the scattering data, which can be solved to obtain approximate solutions of the perturbed system. A comprehensive review of the IST-based PT for solitons in nearly integrable models was given by Kivshar & Malomed (1989).

An alternative multi-soliton PT is based on using a Green function (GF) for the underlying equation linearized around the unperturbed multi-soliton solution (Keener & McLaughlin, 1977). If the zero-order approximation is integrable, this method is equivalent to the IST-based PT, as the GF can be constructed—by means of IST—around any exact multi-soliton solution. Although this approach has the advantage of being directly formulated in terms of physical parameters (soliton speeds, collision delays, breather frequencies, etc.), rather than more abstract IST characteristics (bound-state eigenvalues and reflection coefficients), finding the GF can be computationally demanding. Methods based on the Bäcklund transformation may ease some of these difficulties (McLaughlin & Scott, 1978).

The GF method often works for one-soliton problems in non-integrable models, as a full set of eigenmodes can often be found for an equation linearized about a soliton even if the equation is not integrable. An example is the nonlinear Klein–Gordon equation

$$\phi_{tt} - \phi_{xx} - \phi + \phi^3 = 0, \quad (5)$$

which describes ferroelectric phase transitions, among other applications. A comprehensive account of the GF method for kinks in non-integrable Klein–Gordon equations was given by Flesch & Trullinger (1987).

Another version of PT is based on the variational approximation (VA), which only demands that the full perturbed equation be derivable from a Lagrangian (e.g., the system is conservative), and that a one-soliton solution be available in the absence of perturbations. The method applies to the description of multi-soliton effects in the adiabatic approximation, representing the wave field as a linear superposition of unperturbed solitons. Inserting this approximation into the model's Lagrangian and integrating over the spatial coordinate, one arrives at an effective Lagrangian, which is a function of the solitons' parameters (amplitude, velocity, and central coordinate and phase) and their first derivatives in time. Application of the Euler–Lagrange variational procedure to the effective Lagrangian then generates a system of ODEs that govern the evolution of the solitons' parameters. Because the linear-superposition assumption underlying VA is not valid in the general case (when solitons strongly overlap in the course of the interaction), a VA is restricted to cases when the solitons interact staying

far apart or when they collide with a large relative velocity.

An early review of results obtained for multi-soliton interactions by means of a VA was given by Gorshkov and Ostrovsky (1981), and an up-to-date review, including the interaction problems, was given by Malomed (2002). There is also an intermediate version of PT, which is based on IST for one soliton, but treats the interaction between solitons, even in an integrable equation, as a perturbation, assuming that the solitons are far separated. By means of this technique, Karpman and Solov'ev (1981) analyzed the interaction between solitons in the NLS and SG equations. Their results for NLS solitons were later checked in a direct experiment with solitons in a nonlinear optical fiber.

The approach based on the linear-superposition approximation for widely separated solitons makes it possible to calculate an effective potential of the interaction between solitons. To this end, one should isolate a part of the model's potential energy which depends on the separation between the solitons. For instance, the potential energy corresponding to the unperturbed SG equation (1) is

$$\Pi = \int_{-\infty}^{+\infty} \left[\frac{1}{2} \phi_x^2 + (1 - \cos \phi) \right] dx. \quad (6)$$

In the vicinity of the first kink, the field is approximated as $\phi_1(x - \xi_1) + \delta\phi_2(x - \xi_2)$, where $\delta\phi_2$ is a small tail of the second kink (both are taken with $c = 0$). Thus, in the lowest approximation, the contribution to the interaction potential from the vicinity of the first kink [which is, say, $-\infty < x < \Xi \equiv (1/2)(\xi_1 + \xi_2)$] is

$$\begin{aligned} U_1 &= \int_{-\infty}^{\Xi} [(\phi_1)_x (\delta\phi_2)_x + (\sin \phi_1) \delta\phi_2] dx \\ &\equiv \int_{-\infty}^{\Xi} [-(\phi_1)_{xx} + \sin \phi_1] \delta\phi_2 dx + (\phi_1)_x \delta\phi_2 \Big|_{-\infty}^{\Xi}, \end{aligned} \quad (7)$$

using integration by parts. A key observation, which holds in much more general situations, is that the integral term in (7) identically vanishes, as $\phi_1(x)$ is an exact stationary solution of the SG equation; hence, all the contribution comes solely from the last term in (7). This yields the interaction potential, $U = U_1 + U_2 = 32\sigma_1\sigma_2 \exp(-|\xi_1 - \xi_2|)$. Noting that each kink is a quasi-particle with mass $m = 8$, this potential provides for full dynamical description of two- or multi-kink systems.

The derivation of the interaction potential based on the same principles applies to several other cases, including two- and three-dimensional solitons (Malomed, 1998). In the case of NLS solitons, the interacting pair is characterized by distance and relative phase between them, a peculiarity being that an effective mass corresponding to the phase difference is *negative*, which strongly affects stability of two-soliton

Figure 1. The breather's breakup into a kink-antikink pair as a result of the collision with another fast kink; shown is the field $\partial\phi/\partial x$. Panels (a) and (b) pertain to the polarities $\sigma = -1$ and $+1$ of the fast kink.

bound states induced by perturbations (Malomed, 2002).

The simplest nontrivial example of the two-soliton interaction is fusion of a $k\bar{k}$ pair as a result of collision. An analysis of this problem is outlined here for the case of small γ and α in (1). Because the collision-induced energy loss responsible for fusion is proportional to the dissipation (α) and can be found to be $\Delta E = 8\pi^2\alpha$, fusion occurs if the steady-state velocity given by (4) is small enough. This means that $|\gamma| \ll \alpha$ whereupon Equation (4) yields $c_0 \approx \sigma\pi\gamma / (4\alpha)$, the corresponding net kinetic energy of the pair being $E_{\text{kin}} = 8c_0^2$. The collision results in pair annihilation if $E_{\text{kin}} < \Delta E$, or $\gamma < \gamma_{\text{cr}} \equiv 4\alpha^{3/2}$.

As shown in Figure 1, the collision of a breather with a moving kink may produce another interesting result in the same model: the breather may be split into a $k\bar{k}$ pair. The final result takes a simple form if the kink is ultrarelativistic, that is, c_0 is close to the limiting value 1: the breakup of the breather (3) into a $k\bar{k}$ pair is possible if $(\pi/2) - \mu < 2.91\sqrt{\alpha}$.

Some special types of conservative perturbations may greatly alter the dynamics. For instance, if the perturbation in the SG equation is $\varepsilon \sin(\phi/2)$ (double SG equation), free 2π -kinks do not exist; instead, their pairs form bound states (4π -kinks), $\phi_{4\pi} = 4 \tan^{-1}(\sqrt{|\varepsilon|/2} \sinh x)$. It is possible to excite vibrations of this bound state, the eigenfrequency of which is $\sqrt{|\varepsilon|}$, as predicted by PT.

A typical example of two-soliton interactions generating radiation loss is the collision of two kinks (which may have both opposite and equal polarities) with a relative velocity c , the perturbing term in the SG

equation being $\varepsilon \sin(2\phi)$. In the ultra-relativistic case, it can be shown directly that the radiation loss appears at order ε^2 and is the same for the $k\bar{k}$ and $k\bar{k}$ pairs. If the relative velocity of the collision is small, the $k\bar{k}$ pair may annihilate into a breather through the radiation loss, which takes place if $c < c_{\text{cr}} \approx 2.22|\varepsilon|$.

Numerical simulations of $k\bar{k}$ collisions in non-integrable models, including Equation (5), reveal an interesting effect. There is a (probably infinite) set of critical relative velocities $c_{\text{cr}}^{(n)}$, $n=0, 1, 2, \dots$, such that the annihilation takes place in intervals $0 < c < c_{\text{cr}}^{(0)}$, $c_{\text{cr}}^{(0)} < c < c_{\text{cr}}^{(1)}$, $c_{\text{cr}}^{(1)} < c < c_{\text{cr}}^{(2)}$, ..., while in transmission windows between them, $c_{\text{cr}}^{(0)} < c < c_{\text{cr}}^{(1)}$, $c_{\text{cr}}^{(1)} < c < c_{\text{cr}}^{(2)}$, ..., the collision is quasi-elastic.

An explanation for this effect is that the kink has an eigenmode of its internal oscillations, and the dominant collision-induced energy loss is caused not by the emission of radiation but by excitation of the internal mode. An ODE model of a variational type makes it possible to explain the alternating annihilation and transmission windows as a result of resonant transfer of kinetic energy of the colliding kinks into their internal modes and back (Campbell et al., 1986).

MYELINATED NERVES

While smooth nerve fibers are common to invertebrates, for example, the giant axon of the squid (Hodgkin & Huxley, 1952), myelinated nerve fibers are widely found in vertebrates. A myelinated fiber is mainly composed of a membrane—interfacing the intracellular space and the extracellular one—surrounded by a myelin sheath which acts as an insulator (Waxman et al., 1995; Koch, 1998; Scott, 2002). This sheath, formed of Schwann cells, is periodically absent in gaps called nodes of Ranvier, making a nerve fiber a discrete and periodic structure, as illustrated in Figure 1. Therefore, ion currents through the membrane can only occur at the nodes of Ranvier, which implies a “saltatory” conduction, under which the wave of activity leaps from one node to the next.

One of the main constraints of neural processing is to develop robust and high-speed traveling waves. Compared with smooth fibers, myelinated structures allow an increased velocity of nerve impulses, while decreasing the diameter of the nerve fiber. Thus, the motor nerves of vertebrates may comprise several hundred individual saltatory fibers. For instance, the information transfer rate (bits/s) in a rabbit’s sciatic nerve is about 1500 times greater than in a squid axon of the same diameter. In the context of biological evolution, it is interesting to know the link between internode spacing and impulse velocity, and whether this link is optimized in terms of speed and robustness. To this end, a mathematical model can provide some answers.

A single myelinated nerve can be modeled from Kirchhoff’s law analysis by the system of difference-differential equations

$$\begin{aligned} V_n - V_{n+1} &= RI_n, \\ I_{n-1} - I_n &= C \frac{dV_n}{dt} + I_{\text{ion},n}. \end{aligned} \quad (1)$$

In these equations, the index n indicates successive active nodes, each of which is characterized by a transverse (inside to outside) voltage across the membrane (V_n). A second dynamic variable is the current (I_n) flowing longitudinally through the fiber from node n to node $n+1$. Also, R is the sum of the inside and outside resistances between two nodes and is inversely proportional to the internode spacing s , and C is the membrane capacitance of a node.

To study the velocity of an impulse, it is sufficient to focus on its leading edge. Thus, we assume that

Figure 1. Sketch of a myelinated nerve fiber.

the sodium ion (Na^+) current begins without delay, and the potassium (K^+) permeability remains equal to its resting value. In this case, the expression of the ion currents developed by Alan Hodgkin and Andrew Huxley (See **Hodgkin–Huxley equations**) can be reduced to the simple and yet physically reasonable expression:

$$I_{\text{ion},n} = I_{\text{Na},n} = \left(\frac{G}{V_b(V_b - V_a)} \right) \times V_n(V_n - V_a)(V_n - V_b), \quad (2)$$

where V_a is a threshold potential, V_b is the Nernst potential, and G is the total ionic conductance near V_b .

The parameters of this model can be related to experimental measurements on a real myelinated nerve fiber (Binczak et al., 2001). From studies on frogs’ motor nerves with a diameter of 14 μm , $R = 28 \text{ M}\Omega$, $C = 3.7 \pm 1 \text{ pF}$, $G = 0.57 \text{ }\mu\text{S}$, $V_a \sim 25 \text{ mV}$, and $V_b = 122 \text{ mV}$, while the distance between nodes equals 2 mm.

In order to study the influence of the internode spacing s on the impulse velocity, s and therefore R become variable. A discreteness parameter D can be defined by setting $R_f = 28 \text{ M}\Omega$, as

$$D \equiv \frac{2 \text{ mm}}{s} = \frac{R_f}{R}, \quad (3)$$

so that $D = 1$ implies the discreteness of a standard frog nerve. Using dimensionless voltage variables $v_n \equiv V_n/V_b$ and $a \equiv V_a/V_b$, the dynamic equation becomes

$$\begin{aligned} D(v_{n+1} - 2v_n + v_{n-1}) \\ = R_f C \frac{dv_n}{dt} + \frac{R_f G}{1-a} v_n(v_n - a)(v_n - 1), \end{aligned} \quad (4)$$

Equation (4) has been used to compute the wave front velocity, which is plotted against D in Figure 2.

If the internodal spacing is small enough, that is, $D \gg 1$, the relative change in voltage between nodes satisfies the inequality $|(v_{n+1} - v_n)/v_n| \ll 1$ and the voltages and currents are smooth functions of distance. Letting $ns \rightarrow x$ in this continuum limit, the system can be described by the partial differential equation

$$s^2 D \frac{\partial^2 v}{\partial x^2} - R_f C \frac{\partial v}{\partial t} = \frac{R_f G}{1-a} v(v-a)(v-1), \quad (5)$$

which is the Zeldovich–Frank–Kamenetsky (ZF) equation. Initially formulated as a model for flame front

Figure 2. Leading edge impulse velocity on a myelinated axon as a function of the discreteness parameter D . The dot-dashed line indicates the continuum limit of Equation (6). The dashed line indicates the saltatory limit in Equation (8). Crosses indicate numerical results.

propagation, this equation is extensively used to study simple unmyelinated nerve models.

In the continuum limit, the wave speed u tends toward u_c (Zeldovich & Frank-Kamenetsky, 1938), where

$$u_c = s \left(\frac{1 - 2a}{\sqrt{2(1 - a)}} \right) \sqrt{\frac{G}{RC^2}}, \quad (6)$$

corresponds to the dot-dashed line in Figure 2. As illustrated in this figure, the continuum approximation holds for $D > 5$.

Propagation failure (Keener, 1987) occurs when the distance between the active nodes becomes too large, that is, when D is above a critical value D^* . This critical value of the discreteness parameter is given to lowest order in a as (Erneux & Nicolis, 1993)

$$D^* \approx \frac{R_f G a^2}{4(1 - a)}. \quad (7)$$

For D slightly larger than D^* , the impulse velocity $u \rightarrow u_s$, where

$$u_s = \frac{s}{\pi C} \sqrt{\frac{G(D - D^*)}{R_f(1 - a)}}, \quad (8)$$

which corresponds to the dashed line in Figure 2.

When $D = 1$, the impulse velocity of a normal frog nerve has been calculated to be equal to 29 m/s, which matches the experimental results (Tasaki, 1982). The large dot in Figure 2 shows that the velocity is close to the maximum possible value, suggesting an optimal evolutionary design.

Failure of an impulse is expected to occur at an internode spacing of 1 cm, corresponding to $D = 0.2$, whereas the normal nerve is designed for $D = 1$, corresponding to a spacing of 2 mm. Thus, the process of evolution has provided a comfortable safety margin against accidental failure on the frog's motor nerve.

Because the impulse velocity reaches its maximum value near $D = 1$, we have an explanation for the fact that the conduction velocity of a frog's myelinated motor nerve is insensitive to the internode spacing. From an engineering perspective, operating in this region of parameter space makes the system robust. These observations are extendable to other myelinated fibers (Scott, 2002).

Finally, it should be noted that the transmission of an individual impulse expends much more energy on a smooth fiber, suggesting an additional reason that myelinated nerve fibers may have played an important role in the course of biological evolution.

NAVIER-STOKES EQUATION

In 1822, the French engineer Claude Navier derived the Navier-Stokes equation, as an extension of Euler's equation to include viscosity. Navier was initially interested in blood flow, and he used a molecular approach to arrive at the viscous terms. Navier's equations were generalized to a compressible fluid by Poisson (1829), and one can find fully continuous derivations by De Saint-Venant (1843). A comprehensive treatment was given by George Stokes in 1845, who independently arrived at the results of Poisson and Saint-Venant using a continuous model. Stokes used the common assumption of linear relations between stress and strain rate and discovered "Stokes' law" for the terminal velocity of objects descending in fluids, which he deduced from experiments with slowing pendulums in viscous media.

The Navier-Stokes equation derives from a general equation for the conservation of momentum, balancing forces per unit volume on both sides. It is given by

$$\rho \frac{d\mathbf{v}}{dt} = \rho \mathbf{g} - \nabla p + \mu \left(\nabla^2 \mathbf{v} + \frac{1}{3} \nabla \nabla \cdot \mathbf{v} \right), \quad (1)$$

where $\mathbf{v}(\mathbf{r}, t)$ is the velocity vector in a cartesian coordinate system, $\rho(\mathbf{r}, t)$ is the density, $\mathbf{g}$ is the acceleration due to external forces (for example, gravitational, magnetic, electro-static forces), $p(\mathbf{r}, t)$ the pressure, and μ the viscosity coefficient. The material derivative is given by

$$\frac{d\mathbf{v}}{dt} = \left(\frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla \right) \mathbf{v}, \quad (2)$$

where the first and second terms are the local time derivative of the quantity $\mathbf{v}(\mathbf{r}, t)$ with spatial coordinates fixed, and the convective (or advective) term accounting for the change of the quantity $\mathbf{v}(\mathbf{r}, t)$ at $\mathbf{r}$ due to the observer following the motion of the fluid with

velocity $\mathbf{v}$. Both terms together are called the material derivative or convective derivative and are usually denoted by d/dt .

In an inertial coordinate system, the acceleration $\mathbf{g}$ originates solely from the gravitational potential of the Earth. Assuming a homogeneous mass at the center of the Earth, the acceleration $\mathbf{g}$ in Equation (1) is given by $\mathbf{g} = g\mathbf{k}$, where $\mathbf{k}$ is the local vertical direction, pointing to the center of gravity of the earth and g is the gravitational acceleration (982.1 cm s^{-2}), which is assumed constant in the first approximation. In a rotating coordinate system, the acceleration $\mathbf{g}$ consists of the centrifugal force and Coriolis force in addition to the gravitational acceleration, see Lamb (1906). Also, for large-scale processes, it is often necessary to account for tidal forces of the moon and sun. The term $-\nabla p$ is the force per unit volume due to a pressure gradient of the scalar pressure field $p(\mathbf{r}, t)$ acting on an infinitesimal volume of fluid with infinitesimal mass.

The last two terms of Equation (1)

$$\frac{\mu}{\rho} \left(\nabla^2 \mathbf{v} + \frac{1}{3} \nabla \nabla \cdot \mathbf{v} \right), \quad (3)$$

are the frictional terms which derive from a shear stress tensor for a Newtonian viscous fluid with constant viscosity coefficients. A fluid is called Newtonian if there is a linear relation between stress and rate of strain assuming isotropy, which is true for the most common conditions. Non-Newtonian fluids have more complex molecular structure or are mixtures of fluids.

The frictional term $\nabla^2 \mathbf{v} = \nabla \nabla \cdot \mathbf{v} - \nabla \times (\nabla \times \mathbf{v})$ contains effects due to compression and rotation. If the fluid is incompressible then the divergence terms are missing from Equations (1) and (3), since $\nabla \cdot \mathbf{v} = 0$. Often the coefficient of kinematic viscosity $\nu = \mu/\rho$ is used instead of the viscosity μ . The viscosity of the fluid depends on temperature, and a table for typical values of viscosity μ , kinematic viscosity ν , and density ρ is shown in Table 1 for typical temperatures. If the temperature across the medium is not uniform then a variable viscosity may have to be accounted for (see Batchelor, 1970).

T (°C)	Air ρ (g cm ⁻³)	μ (g cm ⁻¹ s ⁻¹)	ν (cm ² s ⁻¹)	Water ρ (g cm ⁻³)	μ (g cm ⁻¹ s ⁻¹)	ν (cm ² s ⁻¹)
0	1.293×10^{-3}	1.71×10^{-4}	0.132	0.999	1.787×10^{-2}	1.787×10^{-2}
10	1.247×10^{-3}	1.76×10^{-4}	0.141	0.999	1.304×10^{-2}	1.304×10^{-2}
20	1.205×10^{-3}	1.81×10^{-4}	0.150	0.998	1.002×10^{-2}	1.004×10^{-2}

Table 1. Density ρ , viscosity μ and kinematic viscosity ν of air and water.

For an ideal (perfect) fluid without internal shear stress, the momentum equation reduces to Euler’s equation of motion for $\mu = 0$. Note that if the flow is irrotational ($\nabla \times \mathbf{v} = 0$) and incompressible ($\nabla \cdot \mathbf{v} = 0$), it essentially behaves as if it is inviscid ($\mu = 0$), because of the incompressibility condition $d\rho/dt = -\rho \nabla \cdot \mathbf{v} = 0$. (Note that a fluid may be incompressible yet ρ may not be constant.)

The system of Equations (1) comprises three momentum equations, together with an additional equation for mass conservation; a thermodynamic equation of state; a relation of pressure, density, and either temperature or entropy; and an energy equation for the additional thermodynamic variable (temperature or entropy). These provide six scalar equations for the determination of the six independent variables, velocity $\mathbf{v}$, density ρ , pressure p , and temperature or entropy as functions of space $\mathbf{x}$ and time t . If the fluid is incompressible, the equation of state becomes obsolete and only four equations are needed, the three momentum equations and the equation for conservation of mass.

Numerical Problems

As with most complicated nonlinear partial differential equations, the Navier–Stokes equation is solved numerically to model a specific fluid flow that is of interest experimentally and theoretically. Because there are many different ways to write the Navier–Stokes equation, the first numerical difficulty is to pick the formulation most suitable to the numerical technique that one wishes to employ and the dimensions of the model. One distinguishes between two-dimensional and three-dimensional models. For two-dimensional incompressible Navier–Stokes equation, for example, there are four different kinds of formulations: the primitive-variable (velocity and pressure), stream function-vorticity, stream function, and velocity-vorticity formulation.

It is important to distinguish between the real dissipation ($\mu \neq 0$), given by the last term of Equation (1) and numerical dissipation, which is introduced by an accumulative error due to the limited order of accuracy of any numerical model. As the numerical dissipation of a good model is often negligible, it is sometimes appropriate to introduce an artificial viscosity that acts

to damp growing high wave number modes, which can lead to numerical instability.

Euler’s equation conserves linear and angular momentum and energy, so it is necessary to verify that the numerical model conserves these conserved quantities and preserves symmetry. In cases where it is not possible to satisfy all these requirements, properties that are most essential to the physical problem are given priority. In order to satisfy such conserved quantities, it is important that the numerical scheme treats the nonlinear convective term

$$\mathbf{v} \cdot \nabla \phi \tag{4}$$

in a conservative manner, where ϕ represents the scalar quantity that is convected and could be one of the three velocity components u, v, w or density ρ in the conservation of mass. Expression (4) is known as the convection form and is nonconservative numerically, since fluxes across mesh boundaries do not cancel. The convection form thus represents a major flaw of every numerical scheme. The most commonly used corresponding conservative formulation is

$$\nabla \cdot (\mathbf{v}\phi), \tag{5}$$

which is also known as the divergence form. Recently it was shown that the skewsymmetric form

$$\frac{1}{2} \mathbf{v} \cdot \nabla \phi + \frac{1}{2} \nabla \cdot (\mathbf{v}\phi)$$

has advantages, because it reduces aliasing errors (see below) for yet unknown reasons and is preferable to the popular rotational form

$$(\nabla \times \mathbf{v}) \times \mathbf{v}.$$

It is important to note that although both equations (4) and (5) are formally equivalent, they are not in a corresponding numerical scheme and care must be taken to avoid this common pitfall when modeling equations that contain convective terms such as the Navier–Stokes equation or the equation for mass conservation (see Hirsch, 2000).

Nonlinear terms such as $\mathbf{v} \cdot \nabla \mathbf{v}$ also generate aliasing errors. These are high-frequency wave number modes appearing or being “aliased” as low-frequency modes that deteriorate the wave number spectrum and eventually lead to numerical blow-up.

Because a numerical model of the Navier–Stokes equation is coupled spatially and temporally, it is

helpful to approximate the spatiotemporal scales of the dynamics. One should determine whether the spatial and temporal scales are equal to, smaller, or larger than each other. If, for example, the temporal scale is larger than the spatial scale, it is sufficient to use low order integration in time such as finite-difference methods, and if smaller or equal, then higher-order temporal integration such as spectral methods becomes necessary. In a temporally extensive computation, it is sometimes possible to revert to finite differences, choosing a relatively small time-step.

Especially difficult numerical problems arise when it is necessary to invert nondiagonal, nonsparse, nontrivial matrices, for example, in implicit time integrations or inverting the Laplacian. In such cases iterative techniques using preconditioning and multi-grid methods have been successfully employed. Complications arising from specifying the correct boundary conditions to use along boundaries of the physical domain should also be mentioned.

Although the Navier-Stokes equation is a very good model for a real fluid, it is important to have an understanding of the process or phenomenon that one wishes to model as well as a sound knowledge of the applicability of the numerical methods that one wishes to employ to be able to faithfully represent the physical dynamics of the fluid.

Phenomena

A salient feature of the Navier-Stokes equation is the phenomenon of turbulence. Due to viscous effects the flow of a real fluid can be observed in two very different states: a laminar state and a turbulent state.

Turbulence induces a cascade to fine scales that are eventually dissipated. It is important in many engineering applications, as a loss of energy means increased costs and can possibly cause damage to the structural body that comes in contact with the fluid or which moves through the fluid (e.g., optimization of airfoils, loss of lift force due to turbulence and boundary layer separation).

Closely related to the phenomenon of turbulence is boundary layer theory and boundary layer separation. Fluid flowing past a surface at rest relative to the fluid will experience friction at the surface of the material, and for the velocity field to be continuous, it is required that the normal as well as tangential fluid velocity vanish at the material surface ($\mathbf{v} = 0$). For an idealized fluid ($\mu = 0$), only the normal velocity has to vanish.

It was the problem of matching the vanishing flow at the surface boundary to some nonzero fluid flow away from the boundary that led Prandtl (1905) to introduce the concept of boundary layer, which is a small "inner" fluid layer close to the surface where viscous effects dominate the flow. This inner layer is joined to an "outer" layer, where the

fluid can be considered inviscid. The concept of boundary layer has led to great progress in fluid mechanics and perturbation methods, where matched asymptotic expansions feature prominently, but a complete understanding of boundary layer separation and its connection to turbulence is still missing.

A useful concept is vorticity, which can be regarded as a beautiful generalization of fluid motion. Formally vorticity is defined as

$$\boldsymbol{\omega} = \nabla \times \mathbf{v},$$

which simplifies to twice the angular velocity for solid body rotation. A fluid is called irrotational if its vorticity is zero and rotational if it is not. Taking the curl of Euler's equation ($\mu = 0$) for an incompressible fluid in the absence of baroclinicity (and after some vector algebra) leads to the vorticity equation

$$\frac{d\boldsymbol{\omega}}{dt} - \boldsymbol{\omega} \cdot \nabla \mathbf{v} = 0.$$

Vortex lines and vortex strength are conserved, vortex lines move with the fluid, and an initially irrotational flow remains irrotational. Associated to vortices and turbulence is the, still not understood, phenomenon of vortex breakdown (Benjamin, 1978).

Among wave phenomena, the most striking is definitely the solitary wave, which appears as a nonlinear wave in a fluid internally as well as at fluid surfaces or interfaces. For free-surface wave phenomena, see Johnson (1997) and the references therein, and for a colorful overview, see Lighthill (1978). A beautiful picture gallery of fluid phenomena can be found in Van Dyke (1982). Other phenomena that can only be listed here include cavitation and thermal convection (Rayleigh-Bénard convection), sub- and supersonic flow, shock waves as well as most instability mechanisms and phenomena (Rayleigh-Taylor instability, Kelvin-Helmholtz instability, barotropic and baroclinic instability).

N-BODY PROBLEM

The Newtonian N -body problem of celestial mechanics is a mathematical generalization of the solar system. In the Euclidean space $\mathbb{R}^3$, consider N points of masses $m_i > 0$, $i = 1, \dots, N$, which attract each other by a force directly proportional to the product of the masses and inversely proportional to the square of the distance. The equations of motion are given by the $6N$ -dimensional system of differential equations

$$\begin{cases} \dot{\mathbf{q}} = M^{-1} \mathbf{p}, \\ \dot{\mathbf{p}} = \nabla U(\mathbf{q}), \end{cases} \quad (1)$$

where the upper dot represents differentiation with respect to the time variable; $\mathbf{q} = (q_1, \dots, q_N)$ is the configuration of the particle system, with $q_i = (q_i^1, q_i^2, q_i^3)$; giving the coordinates of the point of mass m_i , $\mathbf{p} = M\dot{\mathbf{q}}$ is the momentum, where M is a $3N$ -dimensional square matrix having on the diagonal the elements $m_1, m_1, m_1, \dots, m_N, m_N, m_N$ and zeros in rest; G is the gravitational constant; and $U(\mathbf{q}) = \sum_{1 \leq i < j \leq N} \frac{m_i m_j}{|q_i - q_j|}$ is the potential function, $-U(\mathbf{q})$ representing the potential energy. Standard re-

Figure 1. The Eulerian solutions of the three-body problem.

sults of the theory of differential equations ensure the existence and uniqueness of an analytic solution for any initial value problem as long as the initial data do not belong to the collision set $\Delta = \bigcup_{1 \leq i < j \leq N} \Delta_{ij}$, where $\Delta_{ij} = \{q \in \mathbb{R}^{3N} | q_i = q_j\}$.

Isaac Newton formulated this problem in his master work *Principia*, but Leonhard Euler was the first to write the equations as we know them today. The case $N = 2$, also called the Kepler problem, is completely solved (see Albouy (2002) for a recent discussion of some early solutions). The relative motion of one body with respect to the other is planar and, depending on the initial conditions, can be a circle, an ellipse, a parabola, a branch of a hyperbola, or a line, in which case a collision takes place in the future or in the past. Kepler's laws (See *Celestial mechanics*) can be recovered from Equation (1).

For $N \geq 3$, very little is known about the N -body problem in spite of thousands of research papers written over more than three centuries. The case $N = 3$ was the most studied since many of the results obtained could be generalized to any larger N . The first attempts to understand the three-body problem were quantitative, aiming at finding explicit solutions. In 1767, Euler found the collinear periodic orbits, in which three bodies of any masses move such that they oscillate along a rotating line (Euler, 1767, Figure 1) and in 1772, Joseph-Louis Lagrange discovered some periodic solutions that lie at the vertices of a rotating equilateral triangle that shrinks and expands periodically (Lagrange, 1772, Figure 2). Those solutions led to the study of central configurations, for which $\mathbf{q}'' = k\mathbf{q}$ for some constant $k > 0$. Each central configuration provides a class of periodic orbits.

Another idea was to reduce the order of the system with the help of first integrals. Ten linearly independent integrals are known: three for the center of mass, three for the momentum, three for the angular momentum, and one for the energy (see Wintner, 1947). Together with a certain symmetry, these integrals allow the reduction of the three-body problem from dimension 18 to 7. But unfortunately the dimension of the problem cannot be further reduced. In 1887, Heinrich Bruns proved that there exist no more linearly independent integrals, algebraic with respect to $\mathbf{q}$, $\mathbf{p}$ and t (Bruns, 1887), thus showing the limitations of the quantitative methods. This led Henri Poincaré to

Figure 2. The Lagrangian solutions of the three-body problem.

attempt a qualitative approach. His first prolific ideas appeared in a memoir published in 1890 (Poincaré, 1890), for which he was awarded the King Oscar Prize (see Barrow-Green, 1997; Diacu & Holmes, 1996). There he laid the foundations of several branches of mathematics, including dynamical systems, chaos, KAM theory, and algebraic topology.

Poincaré aimed to understand the geometry of the phase space and the relative behavior of orbits and, thus, to answer questions regarding stability, asymptotic motion at infinity, existence of periodic orbits, etc. An important problem in this direction was that of singular solutions, that is, those that tend to the collision set Δ . It took mathematicians almost a century to prove that for $N \geq 5$, there exist singular solutions that do not end in collisions but in pseudocollisions, which are orbits that become unbounded in finite time (see Diacu & Holmes, 1996). For $N = 4$, the problem is still open.

Recently, a lot of interest has been in finding choreographies, that is, periodic orbits for which all the bodies move on the same closed curve. For more than two centuries the only known example was the class of Lagrangian solutions in the particular case that all the masses are equal and the ellipses are circles. With the help of variational methods, in 2000, a spectacular new class was proved to exist: three bodies of equal mass chase each other along a curve resembling the figure eight (Chenciner & Montgomery, 2000; Montgomery, 2001, Figure 3). There is numerical evidence that this periodic orbit is KAM stable, that is, the solutions through most initial conditions in some sufficiently small neighborhood of the orbit stay close to it for all time, while the other solutions leave the neighborhood very slowly. Unfortunately, the stability region seems to be very small. Numerical experiments suggest that the probability of finding an eight in the universe is somewhere between one per galaxy and one per universe. Hundreds of other choreographies have been numerically put into the evidence.

Still far from fully understood are the questions regarding various restricted three-body problems. In the

Figure 3. The figure eight solution of the 3-body problem.

elliptic one, for example, it is asked to determine the motion of one body, assumed to have zero mass, while the other two move on ellipses as in the Kepler problem with negative energy.

Numerical methods are also of help for getting insight into the problem. But due to the apparently chaotic character of the motion, they must be implemented with care. Recently, much progress has been made in successfully applying scientific computation to various aspects of the general and restricted three-body problem.

Many of the ideas of the classical N -body problem can be adapted to related problems for understanding the motion of particle systems given by other potentials, like those of Manev and Schwarzschild (also used in celestial mechanics), Coulomb (atomic and molecular theories), and Lennard-Jones (crystal formation). Based on the Coulomb potential, Niels Bohr's model of the hydrogen atom led to the development of quantum mechanics. Several other branches of science have profited from the study of the N -body problem.

NEPHRON DYNAMICS

The kidneys play an important role in regulating the blood pressure and maintaining a proper environment for the cells of the body. The mammalian kidney contains a large number of functional units, the nephrons. For a human kidney the number of nephrons is of the order of 1 million, and for a rat kidney the number is approximately 30,000. The nephrons are organized in a parallel structure such that the individual nephron only processes a very small fraction of the total blood flow to the kidney. To distribute the blood that enters through the renal artery, the kidney makes use of a network of arteries and arterioles. Closest to the nephron, we have the afferent arteriole that leads the blood to the capillary network in the glomerulus where water, salts, and small molecules are filtered from the blood and into the tubular system of the nephron. On the other side of the glomerulus, the efferent arteriole leads the blood to another capillary system that receives the water and salts reabsorbed by the tubules.

Figure 1 provides a sketch of the main structural components of the nephron. Note how the terminal part of the loop of Henle passes within cellular distances of the afferent arteriole. As described below, this anatomical feature allows for a special feedback regulation.

Figure 1. Sketch of the main structural components of the nephron.

In order to protect its function in the face of a varying blood pressure, the individual nephron disposes of a number of mechanisms to control the incoming blood flow. Most important is the tubuloglomerular feedback (TGF) mechanism that regulates the diameter of the afferent arteriole in response to variations in the NaCl concentration in the fluid that leaves the loop of Henle via the distal tubule. If the salt concentration in this fluid becomes too high, specialized cells (macula densa cells) near the terminal part of the loop of Henle elicit a signal that causes the smooth muscle cells at the downstream end of the afferent arteriole to contract. Hence, the incoming blood flow is reduced, and so is the glomerular filtration rate.

The TGF mechanism represents a negative feedback. However, by virtue of a delayed action associated with a finite transit time through the loop of Henle, the flow regulation tends to become unstable and produce self-sustained oscillations with a period of 30–40 s. While for rats with normal blood pressure, these oscillations have the appearance of a regular limit cycle with a sharply peaked power spectrum, highly irregular oscillations, displaying a broadband spectral distribution with strong subharmonic components are observed for spontaneously hypertensive rats. In a particular experiment, clear evidence of a period-doubling of the pressure oscillations has been found, indicating that the nephronic control system is operating close to a transition to chaos.

Figure 2 displays examples of the tubular pressure oscillations observed for normotensive rats (a) and for spontaneously hypertensive rats (b), respectively. The

Figure 2. Regular (a) and irregular (b) tubular pressure oscillations from a normotensive and a spontaneously hypertensive rat, respectively.

pressure oscillations can be observed by means of a glass pipette inserted into the proximal tubule of a nephron at the surface of the kidney.

The processes involved in the nephron autoregulation are known in considerable detail. Besides the filtration of water and salts in the glomerulus, these processes include the passive (osmotic) and active (enzymatically controlled) processes by which water and salts are reabsorbed along the loop of Henle, the enzymatic processes through which the smooth muscle cells in the arteriolar wall are activated by the macula densa signal, and the dynamic response of the arteriolar wall to external stimulation.

The steady-state response of the TGF mechanism can be obtained from open-loop experiments in which a block of paraffin is inserted into the middle of the proximal tubule and the glomerular filtration rate is measured as a function of an externally forced flow of artificial tubular fluid into the loop of Henle. Reflecting physiological constraints on the diameter of the arteriole, this response follows an S-shaped characteristic with a maximum at low Henle flows and a lower saturation level at externally forced flows beyond 20–25 nl/min.

Together with the delay in the TGF regulation, the steepness of the response plays an essential role for the stability of the feedback system. The length of the delay can be estimated from the phase shift between the pressure oscillations in the proximal tubule and the oscillations of the NaCl concentration in the distal tubule. A typical value is 10–15 s. In addition, there is a transit time of 3–5 s for the signal from the macula densa cells to reach the smooth muscle cells in the arteriolar wall. The result is a total delay of 14–18 s. The steepness α of the steady state response curve is found to be significantly higher for spontaneously hypertensive rats than for normal rats.

By integrating the different physiological processes into a coherent, nonlinear dynamic model, it has been possible to show how these processes together produce the observed behavior, that is, the emergence of self-sustained oscillations as the slope of the response characteristic exceeds $\alpha \approx 11$ and the transition to chaos via sets of overlapping period-doubling cascades as the feedback slope exceeds $\alpha \approx 20$.

Figure 3 shows a two-dimensional bifurcation diagram for the single-nephron model. The dashed curve is a Hopf bifurcation curve. Period-doubling and saddle-node bifurcations are indicated as fully drawn and dotted curves, respectively. As before, T is the total delay in the TGF regulation, and α is the (maximal) slope of the open-loop feedback characteristic.

The single-nephron model can also be used to simulate the response to an external perturbation, for instance, the infusion of artificial tubular fluid into the loop of Henle or the administration of a drug to the rat. This last possibility is rapidly gaining in

Figure 3. Two-dimensional bifurcation diagram for the single-nephron model. The diagram illustrates the complicated bifurcation structure in the region of 1:1, 1:2, and 1:3 resonances between the arteriolar dynamics and the TGF-mediated oscillations. In the physiologically interesting regime around $T = 16$ s, another set of complicated period-doubling and saddle-node bifurcations occur. Here, the nephron is operating close to a 1:4 (or 1:5) resonance.

Figure 4. Example of chaotic phase synchronization for a pair of adjacent nephrons in a hypertensive rat.

significance as the application of simulation models in the development of new drugs becomes more and more important.

A variety of cooperative phenomena that can arise from interactions among the nephrons may also be significant. The functional units are typically arranged in couples or triplets with their afferent arterioles branching off from a common interlobular artery. This structure allows neighboring nephrons to interact via signals that propagate along the arteriolar system. As experiments show, this interaction can lead to various forms of synchronization among the nephrons, including in-phase and antiphase synchronization for regularly oscillating nephrons, and chaotic phase synchronization for nephrons with irregular oscillations. By modeling these coupling phenomena in detail, one may be able to predict the typical size of the synchronization domains and to examine the role that synchronization among the nephrons plays in the overall regulation of the kidney.

Figure 4 shows an example of the tubular pressure oscillations observed for two adjacent nephrons in a hypertensive rat. The transition to synchronization can be observed as a locking of the average periods of the two signals in a 1:1 relation to one another. Alternatively, one can define and follow the temporal

variation of the instantaneous phases for the two signals.

NERVE IMPULSES

The scientific study of nerve impulses goes back to 1791, when Luigi Galvani reported that a frog's leg muscle twitches if the attached nerve is stimulated with a bimetallic contact (Brazier, 1961). This discovery was soon followed by Alessandro Volta's invention of the battery, which launched the science of electrophysiology and raised the question: Does animal electricity differ from chemical electricity?

Among attempts to answer this question was a key experimental study by young Hermann Helmholtz, who cleverly measured the speed of signal propagation on a frog's sciatic nerve (Helmoltz, 1850). In making this measurement, he ignored the advice of his father, a philosopher, who believed that muscular motion was identical to its motivation; thus, any time delay between thinking and doing was theoretically impossible. To the contrary, Helmholtz found a velocity of about 27 m/s, which is much less than the speed at which an electrical signals propagate along conducting wires. Although an outstanding theoretical physicist, Helmholtz was unable to understand why a nerve impulse should move so slowly. Was it the mechanical motion of some molecular substance that he had observed? Interestingly, nonlinear diffusion was suggested as an answer to this puzzle by Robert Luther at the beginning of the 20th century (Luther, 1906).

Among the wonders of electronics that appeared in the 20th century was the cathode-ray oscilloscope

Figure 1. Time course of the transmembrane voltage and membrane permeability of an impulse on a squid nerve. (Courtesy of Kenneth Cole.)

(CRO), which Kenneth Cole used to take the first photograph of a nerve impulse on the giant axon of the squid (see Figure 1) (Cole & Curtis, 1938). Time increases to the right as indicated in milliseconds by the marks on the lower margin, showing that horizontal CRO deflections were not yet uniform in the late 1930s. The solid line is the transmembrane voltage (V), which rises rapidly from a resting level, hesitates at a peak level of about 100 mV, and then falls back more slowly. The width of the band indicates the membrane permeability (or conductivity), which evidently increases greatly during passage of the nerve impulse.

Progress toward explaining these phenomena came soon after the Second World War, taking advantage of the significant advances in electronics during those years. In 1952, Alan Hodgkin and Andrew Huxley presented a series of papers on the squid giant axon, which culminated in a formulation of nerve impulse dynamics based on an empirically determined reaction-diffusion system, from which all details of Figure 1 were computed (Hodgkin & Huxley, 1952). In this Hodgkin-Huxley (HH) model, the initial rise of transmembrane voltage is caused by an influx of positively charged sodium ions, and the maximum voltage is attained when the inward diffusion of sodium ions is balanced by outward conduction current through the membrane. On a longer time scale, positively charged potassium ions flow out of the nerve, bringing the transmembrane voltage back to its resting value, whereupon it is ready to conduct another impulse. Thus, the means by which squid nerves carry signals are explained by the nonlinear reaction-diffusion system

$$\frac{\partial^2 V}{\partial x^2} - r c \frac{\partial V}{\partial t} = r j_{\text{ion}}, \quad (1)$$

where r is the series resistance per unit length of the axon core, c is the capacitance per unit length, and j_{ion} is a rather complicated expression for the transmembrane ionic current per unit length.

Figure 2. A squid giant axon and the sciatic nerve of a rabbit, to the same scale. (Data from Young, 1951).

In thinking about the HH formulation, it is important to be aware that a squid nerve differs from the sciatic nerve of the frog, which Galvani and Helmholtz studied. A sciatic nerve is actually a bundle of smaller fibers, whereas the squid nerve is a single “giant” axon. The squid nerve is uniform along the propagation direction; thus, the HH system is based on the partial differential equation system of Equation (1). The individual fibers of a sciatic nerve, on the other hand, are covered with an insulating layer (myelin) except at rather widely spaced active nodes (nodes of Ranvier). Thus, impulse propagation on a myelinated axon is described by a difference-differential equation, in which the wave of activity jumps from node to node (saltatory conduction). Among other differences, this means that impulse conduction velocity increases as the square root of diameter of a squid fiber, while it is roughly proportional to the first power of the diameter of a myelinated fiber. Importantly, the energy expended in transmitting a nerve impulse is much less in a myelinated fiber than in a smooth one.

These qualitative differences are emphasized in Figure 2, which compares a typical squid nerve with the sciatic nerve of a rabbit. The rabbit nerve contains about 375 small (myelinated) axons, each of which can conduct an impulse at up to 80 m/s, or about four times faster than a squid axon, leading to an increase in data transmission capacity of about three orders of magnitude. This dramatic increase in information carrying capacity is typical in vertebrate motor neurons, which are myelinated nerve bundles.

From an analytic perspective, the HH formulation is rather complicated, as it involves five dynamic variables, each of which depends on both longitudinal position and time. These are transmembrane voltage, axial current, sodium turn-on and turn-off variables, and a potassium turn-on variable. Thus, it has been of interest to consider other formulations that preserve qualitative properties of the HH system while simplifying their structure.

In the most simple approximation, the transmembrane ionic current is assumed to be a cubic nonlinear

function of the transmembrane voltage; thus,

$$j_{\text{ion}} \approx \left(\frac{g}{V_{\text{th}} V_{\text{max}}} \right) V(V - V_{\text{th}})(V - V_{\text{max}}), \quad (2)$$

where V_{th} is a threshold voltage and V_{max} is the amplitude of the impulse. Under this approximation, the HH dynamics reduce to the Zeldovich–Frank–Kamenetsky (ZF) equation, which describes the leading edge of an impulse but misses the return of the voltage to its resting value. From this perspective, a zero-order estimate of the impulse velocity is of order $\sqrt{g/rc^2}$. Several analytic formulas for the dependence of impulse velocity on axon parameters have been obtained under the ZF approximation (Scott, 2002).

A simple way to represent recovery was developed by Vladislav Markin and Yuri Chizmadzhev in the 1960s (Markin & Chizmadzhev, 1967). Under this MC approximation, a prescribed time course of transmembrane ionic current is assumed to be triggered if the membrane potential reaches a threshold variable. This prescribed current is a negative (inward) current (j_1) maintained for a time τ_1 followed by a positive (outward) current (j_2) maintained for a time τ_2 . (The condition $j_1\tau_1 = j_2\tau_2$ then ensures that the net charge crossing the membrane during an impulse is zero.) With appropriate parameters, the MC model yields a recovering impulse having approximately the speed and threshold properties of the HH impulse.

To bring dynamics into the picture without invoking the complexities of the full HH model, Jin-Ichi Nagumo and his colleagues used a membrane model previously developed by Richard FitzHugh, in which the cubic ionic current of Equation (2) is augmented with a single dynamic recovery variable that drives the membrane voltage back to its resting level (Nagumo et al., 1962). This FitzHugh–Nagumo (FN) system was developed as an electronic equivalent of a nerve axon, which can be regarded as a *neuristor*. In the early 1970s, FN became of interest to applied mathematicians, who were beginning to study the theoretical properties of nonlinear reaction-diffusion systems, and in two or three spatial dimensions it has been used to study the emergence of spiral and scroll waves.

In addition to its inherent complexity, the HH system is driven by an initial influx of sodium ions, whereas the exciting current in many nerve fibers, including dendrites of the human brain, are largely driven by calcium ion current. For many applications, therefore, it is currently of interest to use a version of the model developed by Catherine Morris and Harold Lecar for calcium ion induced membrane switching in the giant muscle fiber of the barnacle (Morris & Lecar, 1981). In this Morris–Lecar (ML) model, $j_{\text{ion}} \approx 2\pi a J_{\text{ml}}$, where a is the axon radius and

$$J_{\text{ml}} = G_{\text{K}n}(V - V_{\text{K}}) + G_{\text{Ca}m}(V - V_{\text{Ca}}) \\ + G_{\text{L}}(V - V_{\text{L}})$$

Figure 3. Plots of the initial ionic current (J_I) and the steady state current (J_{ss}) for a typical Morris-Lecar model (Fall et al., 2002; Scott, 2003).

with m and n being calcium and potassium turn-on variables, respectively. Also G_K , G_{Ca} , and G_L are membrane conductances, and V_K , V_{Ca} , and V_L are equilibrium potentials for potassium, calcium, and “leakage” ions, respectively. The turn-on variables are assumed to obey first-order dynamics as (Fall et al., 2002)

$$\begin{aligned}\frac{dm}{dt} &= -[m - m_0(V)]/\tau_m(V), \\ \frac{dn}{dt} &= -[n - n_0(V)]/\tau_n(V),\end{aligned}$$

where

$$\begin{aligned}m_0(V) &= [1 + \tanh((V - V_1)/V_2)]/2, \\ n_0(V) &= [1 + \tanh((V - V_3)/V_4)]/2\end{aligned}$$

and

$$\begin{aligned}\tau_m(V) &= \tau_{m0} \operatorname{sech}[(V - V_1)/2V_2], \\ \tau_n(V) &= \tau_{n0} \operatorname{sech}[(V - V_3)/2V_4].\end{aligned}$$

At times short compared with τ_n , J_{ml} appears as the cubic function, which is plotted as a dashed line in Figure 3; thus the leading edge of an impulse will propagate as required by the ZF equation. At times long compared with τ_n , $m(t)$ remains equal to $m_0(V)$ and $n(t) \rightarrow n_0(V)$, so

$$\begin{aligned}J_{ml} \rightarrow J_{ss} &= G_K n_0(V)(V - V_K) \\ &\quad + G_{Ca} m_0(V)(V - V_{Ca}) + G_L(V - V_L).\end{aligned}$$

This is a steady state membrane current (plotted as the solid line in Figure 3), which forces the system back to its resting state at

$$[V, m, n] = [V_R, m_0(V_R), n_0(V_R)].$$

For sufficiently large values of τ_{n0} , therefore, the ML equation supports a nerve impulse with recovery.

At the dawn of the 21st century, electrophysiology is becoming a highly sophisticated experimental science,

generating data on ever more intricate neural structures; thus, it will be of interest to consider using these five approaches (HH, ZF, MC, FN, and ML) to understand the dynamics of nerve impulse propagation on axonal and dendritic branching regions of real neurons.

NEURAL NETWORK MODELS

A neural network consists of units and connections corresponding to neurons and synapses in biological neural networks. We focus here on neural network models as a means to better understand the working principles of nervous systems, in particular the human brain. Quantitative modeling is today accepted as a very important tool in neuroscience that has potential to enable understanding of the very complex dynamical

and nonlinear processes underlying the functioning of biological nervous systems. So-called artificial neural networks have been developed mainly for technical applications with little concern for biological plausibility and modeling (Haykin, 1998), and we will not consider them further here.

A computational model may help to explain experimental findings and to make new experimentally testable predictions. By now, most parts of the brain have been modeled, and many different types of models exist of a system, for example, for the hippocampus, an evolutionary old part of cortex important for memory and memory consolidation. When designing a neural network model of a particular system, the constituent neurons and their synaptic connections have to be represented with the desired biophysical detail, for example, as a set of coupled ordinary differential equations that can be solved numerically on a computer (Koch & Segev, 1998; Scott, 2002). The level of biological detail in the models studied ranges from networks of very simple threshold logic units connected by binary weights to networks comprising elaborate compartmental cell models with thousands of compartments and parameters. In addition to the signal transduction and transmission processes of the neuron such a detailed cell model may also represent intracellular processes such as biochemical second messenger cascades and calcium dynamics including, for example, diffusion.

In an accurate network model of a particular system, its constituent neuron types and proportions as well as their synaptic interactions have to be adequately represented. Available data about the system must be collected from literature and experiments and be entered as parameter values. A problem with this approach is that often some part of the information required by the model is lacking, such as the distribution of different kinds of ionic channels over the cell membrane or the details of synaptic plasticity dynamics (for example, augmentation and depression). Thus, some parameters may have to be indirectly inferred, and the models need to be tuned to fit experimental recordings, for example, of the shape of excitatory and inhibitory postsynaptic potentials or neuronal firing patterns at different levels of injected current. This introduces some uncertainty with regard to the validity of the model.

The input to the network from sources outside the model must also be represented in some way. Moreover, conditions and values measured in an *in vitro* preparation like a brain slice, a cell culture, or a piece of isolated spinal cord may differ from those of the intact *in vivo* system, and the latter may be inaccessible.

Nervous systems, other than the most simple ones, typically comprise a very large number of neurons. With today's computers it is feasible to simulate hundreds of thousands of compartments and millions

of synapses at a reasonable level of biophysical detail. For large models the turnaround time for simulations, however, may be in the order of days, so parallel simulators are therefore useful. It is still beyond the capacity of today's supercomputers to handle full scale models of biological networks. A common practice is, therefore, to work with dramatically subsampled network models in which the number of neurons is reduced to a small fraction of those actually present in the target system. As a consequence, the number of input synaptic connections on cells in the model is also dramatically reduced. With cell models tuned to single cell data, for example, with adequate input resistances and thresholds, it will become necessary to compensate by exaggerating the synaptic conductances in order for the model to reproduce the activity seen in the real system. Having few and large synaptic interaction events in the system may, however, distort network dynamics, thus, making the model a poor quantitative representation of the actual system. Such effects should be born in mind when interpreting result from simulations using subsampled models.

Furthermore, one sometimes excludes from the model altogether neuron types known to exist in the actual biological system. For one reason or another a cell type may be considered unimportant for the questions addressed. One example is the neuroglia cells that are on average about ten times more numerous than neurons in the brain. They are thought to mainly serve the purpose of structural support and maintenance of the internal environment and are rarely included in network models. But one cannot entirely exclude that these cells in some situations subserve functions important for signal processing.

At the other extreme from networks of complex multi-compartmental model neurons are neural network models in which the biophysical detail has been reduced to a minimum. Such abstraction serves the important purpose of helping to pinpoint and elucidate the fundamental mechanisms behind the functioning of a complex system, which may enable further theoretical analysis of the phenomena under study.

A network model may be simplified in several different ways. For instance, the neurons can be modeled as point neurons (a single isopotential compartment) lacking geometric extent. Network units may use a graded output (with, for example, a sigmoid transfer function) representing an instantaneous firing frequency, or they may be spiking as real neurons. The former may, in fact, represent the average population activity in a cortical module like a minicolumn rather than an individual neuron. An integrate-and-fire model neuron is a bit more elaborate with a simple membrane dynamics and a spiking threshold (Gerstner, 1999). Whether or not temporal timing at the millisecond range in the spike trains of neurons is fundamental for the information processing in the brain or if a rate code is

adequate for most purposes is presently a hotly debated issue. Yet another class of models is neural continuum field models that represent the neural structure as a continuous sheet of excitable neural tissue with a lattice connectivity (Bressloff et al., 2002).

In simplified network models, the details of synaptic transmission and plasticity may be replaced with weighted inputs and simple learning rules. Signal delays along axons are ignored, which may be reasonable at least for millimeter distances in small networks. Instead of an accurate representation of short- and long-term synaptic plasticity, one typically incorporates a correlation-based learning rule, for example, some form of Hebbian learning (Rolls & Treves, 1997). The adiabatic learning hypothesis (Caianiello, 1961) stating that synaptic weight changes occur on a much slower timescale than the neurodynamics itself, simplifies the model and network dynamics considerably. On the other hand, this assumption is now known to be invalid in, for instance, the neocortex where synaptic properties are modulated on a millisecond timescale.

A modeling strategy that has often proven fruitful is to develop a suite of models at different levels of abstraction for the same neuronal network. The most detailed model relates closely to the biological network under study, and the aim is to transform in a well-defined fashion to gradually more abstract descriptions, using the most abstract ones as the starting point for theoretical analysis.

NEURISTOR

Coined by Hewitt Crane in 1962, the term *neuristor* implies “the whole class of lines that exhibit

attenuationless propagation with recovery” (Crane, 1962). In principal, this definition was intended to include active nerve fibers and even forest fires, but Crane’s motivation was to overcome certain problems associated with the miniaturization of electronic circuits. Based upon a half-dozen reports prepared by Crane and his colleagues at the Stanford Research Institute since the late 1950s, this carefully written paper provides a window into the thinking of electrical engineers at the threshold of the integrated circuit revolution.

As the dimensions of conventional (transistor) computing circuits are greatly reduced, Crane reasoned, at least two design problems must be faced. First, the density of interconnections increases, eventually requiring “a dense set of interconnections at a point.” Second, the resistance per unit length of interconnecting wires may become inconveniently large. (Crane pointed out that the resistance of a 1 μm copper wire is about a 1000 $\Omega/\text{in.}$) Both of these problems may be mitigated by basing miniaturized computer design upon an “active wire” in which energy is stored uniformly over the system and continuously dissipated by nonlinear traveling-wave impulses, rather than at discrete and isolated amplifying elements. Some indication that neuristor design is a promising strategy is offered by the fact that it was selected by evolution for the development of our biological brains.

Being uniform in the direction of propagation, Crane’s active wire supports a traveling-wave impulse in which the rate of energy release is equal to its rate of dissipation. Upon impulse passage, the line remains inactive for a certain time (the refractory period), after which it is able to transmit a new impulse. Because an impulse cannot propagate through a refractory region, two impulses will destroy one another in a head-on collision, and impulses are not reflected from the end of a neuristor line.

If two interconnection junctions are included—both of which seem feasible from an engineering perspective—a neuristor system is logically complete, meaning that it can realize all possible Boolean switching functions. These two neuristor interconnections are as follows. (a) A *T* junction is shown in Figure 1(a). An impulse entering on one of the branches proceeds outward on the other branches. Such a junction is not difficult to realize, requiring merely that the strength of the incoming impulse divided by the number of outgoing branches is above the threshold of the outgoing branches. (b) An *R* junction is shown in Figure 1(b). In an *R* junction, the refractory (or inhibitory) variable of one line is shared with an adjacent line (over the shaded area), while the excitatory variable is not. Thus, individual impulses traveling from A to B (on the upper line) can block individual impulses traveling from D to C (on the lower line) and vice versa. These two junctions can be interconnected in a variety of useful ways,

Figure 1. Some simple neuristor interconnections. (a) *T* junction. (b) *R* junction. (c) *T–R* junction. (d) Analog of a relay or transistor.

one being the *T–R* junction, shown in Figure 1(c). Here impulses incoming on line A will proceed through to C but will not be transmitted to B, effectively isolating the input lines (A and B) from each other.

In considering the switching possibilities of such neuristor systems, Boolean variables can be chosen in either of two ways, indicating the presence or absence of individual impulse or the presence or absence of impulse trains. From the latter perspective, the arrangement in Figure 1(d) can be viewed as equivalent to a relay or a transistor because an incoming impulse train on line C will block the transmission between A and B. As computing systems constructed from relays or transistors are known to be logically complete, it follows that neuristor systems are also logically complete.

The length of the refractory zone of an impulse is equal to the product of its velocity times the recovery interval. This is an important design parameter for a neuristor system, setting the scale for many functions. If a circular section of active line is used as a storage ring, for example, the circumference of this ring must be greater than the length of a refractory zone. Thus an insufficiently short refractory length is a major

limitation on the degree to which a particular neuristor system can be miniaturized.

In his seminal paper, Crane offered several suggestions for neuristor realizations, taking advantage of the variety of interesting nonlinear diode structures that were being invented in the early 1960s—such as Esaki (tunnel) diodes and four-layer diodes. Also suggested was an ingenious combination of *T* and *R* junctions that allows two signal paths to cross without interference and without being lifted from a common substrate.

Although neuristors have been designed and fabricated in various laboratories (Beretovskii, 1963; Yoshizawa & Nagumo, 1964; Sato & Miyamoto, 1967; Parmentier, 1969; Scott, 1970; Reible & Scott, 1975; Nakajima et al., 1976), the neuristor strategy has not been important for the design of modern computing systems. Among other reasons for this failure must be counted the amazing progress in miniaturization of silicon metal-oxide-semiconductor transistors, which are now far smaller than the refractory length of any conceivable neuristor structure.

Beyond applications to electronic computing systems, however, the neuristor design concept may yet aid in understanding the behavior of neural systems, as was suggested by Crane in the early 1960s (Crane, 1964). Indeed, this possibility is more compelling today because dendritic fibers (in addition to axons) are now known to support action potentials and are, therefore, also neuristors in the original sense of the word (Stuart et al., 1999). Thus, possibilities arise for neuristor-like computations in the axonal and dendritic trees of real neurons (Scott, 2002). Neuroscientists studying the intricate networks of interwoven dendro-dendritic, currently being revealed by electron microscopy, may profit from a review of Crane's early work.

NEURONS

Nerve cells, or neurons, are typically comprised of a cell body, dendrites, and an axon. The typical cortical neuron depicted in Figure 1 has both an apical dendrite and several basal dendrites. Dendrites and the soma are the sites at which axon terminals from other neurons make contacts and provide stimulation to a neuron. These sites of contact between neurons are termed synapses. The axon emanates from the cell body and contacts other neurons at distances varying from 1.0 mm up to almost 1 m, depending upon the type and location of the neuron in question. The ends of axons terminate very close to the dendritic and cell body membranes of other neurons to form synapses. When the cell body of a neuron is sufficiently depolarized by its inputs, it reaches the threshold for action potential (or spike) generation, and one or more spikes are triggered. These spikes then propagate along the axon at speeds ranging from less than 1.0 ms^{-1} up to almost 100 ms^{-1} .

Neurons receive both excitatory (depolarizing) and inhibitory (hyperpolarizing) stimulation from the axon terminals that synapse onto them, with a typical cortical neuron having about 10^3 – 10^4 synapses. When an action potential reaches a synapse, it causes the release of neurotransmitter molecules that rapidly diffuse across the very small extracellular space to the membrane of the postsynaptic cell's dendrite or soma. There they bind to receptor molecules and cause ion channels to open resulting in either depolarization (excitatory synapse) or hyperpolarization (inhibitory synapse). These potential changes propagate down the dendrites to the cell body, where they are combined approximately linearly. If this net potential change depolarizes the cell body past a threshold, the neuron will fire one or more spikes. These spikes in turn propagate along the axon of this cell, and the process repeats itself.

Nonlinear Dynamics of Action Potential Generation

In mathematical terms, a series of action potentials is a limit cycle oscillation in the neural state space. There are several distinct dynamical patterns of action potential generation that have been observed, and these will be characterized in terms of their dynamical foundations.

Figure 1. Schematic diagram of a typical neuron in the neocortex. The longest dendrites are between 1–3 mm in length, while the axon can be as short as a few mm or as long as 1.0 m.

As demonstrated by Hodgkin and Huxley (1952) in work that led to the Nobel Prize in 1963, the dynamics of spike generation is based upon two ionic currents: a sodium (Na^+) current that rapidly depolarizes the neuron followed by a slower potassium (K^+) current that repolarizes the neuron. Each current I_j is described by Ohm's law written as the product of a conductance (reciprocal of resistance) g_j and a voltage. For each ion, the voltage term is given by the difference between the membrane potential V and the equilibrium potential for the ion in question, E_j

$$I_j = g_j(V - E_j) \quad (1)$$

Due to the fact that the neural cell membrane functions as a capacitor, the membrane potential V is described by a differential equation of the form

$$C \frac{dV}{dt} = g_{\text{Na}}(V)(V - E_{\text{Na}}) + g_{\text{K}}(V)(V - E_{\text{K}}) + I_{\text{ext}}, \quad (2)$$

where I_{ext} is an external stimulating current (or a synaptic input). For typical cortical neurons, $E_{\text{Na}} = 55 \text{ mV}$ and $E_{\text{K}} = -95 \text{ mV}$. This equation would be linear except for one crucial observation: the two conductances $g_{\text{Na}}(V)$ and $g_{\text{K}}(V)$ are functions of V . This biophysical discovery by Hodgkin & Huxley (1952) means that ion conductances change with the voltage, thereby generating both positive and negative nonlinear feedback that produces the action potential.

A simple set of equations with normalized variables (Wilson, 1999a) can be used to elucidate the essential dynamics of Equation (2):

$$\begin{aligned} \frac{dV}{dt} &= 4 \left(V^2 - \frac{V}{10} \right) (V - 1) + R \left(V + \frac{1}{5} \right) + I_{\text{ext}}, \\ 5 \frac{dR}{dt} &= R + 3V^2 \end{aligned} \quad (3)$$

The term $(V^2 - V/10)$ on the right in the first equation represents the V dependence of the Na^+

conductance as a quadratic function, while the variable R (Recovery variable) represents the K^+ conductance governed by the second equation. Note that the time constant for the second equation is 5 times slower than that in the first equation. Normalization has shifted the resting potential from -70 mV to zero and has set $E_{Na} = 1$ here, which corresponds to 125 mV above the resting potential. Similarly, $E_K = -\frac{1}{5}$, or 25 mV below the resting potential. Finally, the unit of time here corresponds to 0.10 ms to produce spike durations of 1.0 ms. These simplifications make the mathematical analysis significantly easier. A version of these equations with parameter values optimized to describe human neocortical excitatory and inhibitory neurons may be found elsewhere (Wilson, 1999b).

For $I_{ext} = 0$, Equation (3) has three steady states at $V = 0$, $R = 0$ (resting state); $V = \frac{1}{2}$, $R = \frac{3}{10}$; and $V = \frac{12}{25}$, $R = \frac{12}{25}$. In order, these are an asymptotically stable node, a saddle point, and an unstable spiral point. The spike firing threshold occurs for $I_{ext} = 0.012$, where the saddle point and node coalesce in a saddle-node bifurcation to a limit cycle. This permits spike firing at arbitrarily low rates for I_{ext} just above threshold, which is characteristic of human and mammalian cortical neurons (Wilson, 1999a). A spike train for $I_{ext} = 0.013$ is depicted in Figure 2a. Above threshold, spike rate increases monotonically as a function of I_{ext} . Neurons that begin firing at arbitrarily low rates due to a saddle-node bifurcation are known as Class I neurons.

A different form of dynamics characterizes Class II neurons. The simplest example is obtained by replacing the dR/dt equation above with

$$5 \frac{dR}{dt} = R + 2V. \tag{4}$$

For $I_{ext} = 0$, the equations now have a single steady state $V = 0$, $R = 0$. It can be shown that these neural equations undergo a subcritical Hopf bifurcation (Wilson, 1999a) to spiking at $I_{ext} = 0.062$. In this case firing begins at a relatively high spike rate, as arbitrarily low rates are precluded by the nature of the bifurcation to spiking. The original Hodgkin–Huxley (1952) equations, in fact, describe a Class II neuron (the giant axon of the squid).

Neurons in the cortex of humans and other mammals are Class I neurons. Thus, they begin firing at arbitrarily low spike rates (less than one spike per second), and this provides a greatly expanded dynamic range for encoding stimulus intensity into spike frequency. In addition, excitatory cortical neurons (but not most inhibitory neurons) typically have several additional currents that can produce even more complex spiking dynamics. For example, addition of a slow Ca^{2+} current and an even slower Ca^{2+} -driven K^+ current results in a neuron that fires bursts of spikes (Wilson, 1999a,b), as illustrated in Figure 2b.

Figure 2. Spikes generated by neural equations. (a) Periodic spike train generated by Equation (3). (b) Pattern of spike bursts generated by a more complex cortical neuron with additional currents. Both graphs have been transformed back from the normalized form described in the text to reflect the mV range and ms time range actually encountered with cortical neurons.

Conclusions

Action potential dynamics are governed by two processes. Once threshold is reached, a rapid influx of Na^+ ions results in depolarization of the neuron causing the upswing of the spike. This process is described by the first term in the dV/dt equation in (3) above. Following this, the variable R increases, permitting K^+ to pass out of the neuron, thus hyperpolarizing it back toward its resting potential. The limit cycle is generated because the recovery variable R operates on a slower time scale than the very rapid Na^+ depolarization. There is also an inactivation of the Na^+ ion current that contributes to termination of the spike (Hodgkin & Huxley, 1952), but it is not essential to the dynamics of spike generation.

Virtually all brain function involves a dynamical interaction between excitatory and inhibitory neurons. For example, short-term memory circuits involve groups of neurons that are reciprocally interconnected by excitatory synapses, which enables them to continue firing following the cessation of stimulation. This ongoing neural activity makes up the short-term memory store. Inhibition is necessary both to shut off short-term memory activity and to prevent it from spreading to activate other neurons. Indeed, when there is too little inhibition in a brain area due to

an imbalance or injury, the spread of excitation may generate epileptic seizures. Many other examples of excitatory and inhibitory neural circuits may be found elsewhere (Wilson, 1999a; Dayan & Abbott, 2001).

NEWTON'S LAWS OF MOTION

Isaac Newton's treatise *Philosophiae Naturalis Principia Mathematica* (Mathematical Principles of Natural Philosophy), often simply referred to as the *Principia*, was completed in May 1686. Publication and printing were overseen by the astronomer Edmund Halley, and the work became available to the public in 1687. In this work Newton sets out, in effect, a template for classical mathematical physics, the dynamics of particles and rigid bodies in particular. The text starts by defining certain basic quantities such as mass, momentum, inertia, force, and acceleration. Once these have been defined and some of their basic properties described, Newton states his “axioms” or “laws of motion” thus:

Law I: Every body continues in its state of rest, or of uniform motion in a right line, unless it is compelled to change that state by forces impressed upon it;

Law II: The change of motion is proportional to the motive force impressed; and is made in the direction of the right line in which that force is impressed;

Law III: To every action there is always opposed an equal reaction: or, the mutual actions of two bodies upon each other are always equal, and directed to contrary parts.

(We have quoted the established 1729 translation from the original Latin to English by Andrew Motte.)

In modern terms the first law, also known as the law of inertia, and already realized by Galileo, states that uniform translational motion is a “natural” state of motion for a particle or body requiring no cause or outside agent to maintain it. (This was an important departure from Aristotelian physics, which held that all motion required an explanation.) Not so with accelerated motion, according to the second law. If a change in the velocity of motion is to come about, it requires the action of a force acting on the particle or body. Finally, in the third law we have the requirement that if a body, A, is acted upon by a force due to another body, B, then B is subject to a force of the same magnitude but of opposite direction from its interaction with A.

Forces

Newtonian mechanics, then, operates with purely kinematic entities, such as position, velocity, and acceleration, and with a set of new, dynamical entities called forces. Newton's laws of motion instruct us to seek the cause of acceleration, a kinematic quantity, in the total force acting on a particle or body. Force is a dynamic quantity. The mass of the particle or body appears as the constant of proportionality in the relation between force (the cause) and acceleration (the effect). Like accelerations, forces are vectors. If two or more forces act simultaneously, they add vectorially and their resultant gives both the correct magnitude and the correct direction of the net force. Many well-known results about levers, systems with suspended masses, and various simple mechanical machines were immediately subsumed under Newtonian mechanics simply by recognizing that forces behave like vectors upon superposition.

Not only did Newton establish a framework for dynamics—and for much of physics—with his three laws, he provided also a new law of Nature for the attractive force of gravity acting between any two bodies. This development was, in some sense, extraneous to the three laws of motion but without it, the full force of Newton's dynamics might not have been appreciated and embraced. Newton's expression for the force acting on a particle, 1, of mass m_1 located at $\mathbf{x}_1$ due to a particle, 2, of mass m_2 , located at $\mathbf{x}_2$, is

$$\mathbf{F}_{12} = Gm_1m_2\mathbf{e}_{12}/r^2. \quad (1)$$

Here r is the distance between the two particles, $r = |\mathbf{x}_1 - \mathbf{x}_2|$ and $\mathbf{e}_{12}$ is the unit vector pointing from the location of particle “1” to the location of particle “2”, that is, $\mathbf{e}_{12} = (\mathbf{x}_2 - \mathbf{x}_1)/r$. The coefficient G , now known as Newton's universal gravitational constant, has the approximate value $G \approx 6.672 \times 10^{-8} \text{ cm}^3 \text{ g}^{-1} \text{ s}^{-2}$.

The first measurements of G were performed by Henry Cavendish in 1798 using a torsion balance. Expression (1) is fully consistent with Newton's third

law, which demands that $F_{12} = -F_{21}$. Force (1) represents action-at-a-distance in the sense that it does not result from direct contact between contiguous bodies or particles. Newton was severely criticized by his contemporaries for this notion, which they viewed as fanciful and unsubstantiated.

In modern terminology, in the *Principia* Newton accomplished (among many other things) integration of the two-body problem of celestial mechanics, that is, the following system of differential equations, which result by combining Newton's law of gravitation with his second law of motion:

$$m_1 d^2x_1/dt^2 = Gm_1m_2(x_2 - x_1)/|x_2 - x_1|^3, \quad (2a)$$

$$m_2 d^2x_2/dt^2 = Gm_1m_2(x_1 - x_2)/|x_1 - x_2|^3. \quad (2b)$$

Because of Newton's third law, addition of Equations (2) yields

$$m_1 d^2x_1/dt^2 + m_2 d^2x_2/dt^2 = 0, \quad (3)$$

which shows that the total momentum of the system, given by

$$P = m_1 dx_1/dt + m_2 dx_2/dt, \quad (4)$$

is a constant of the motion. Thus, the center of mass of the two particles,

$$R = (m_1x_1 + m_2x_2)/(m_1 + m_2), \quad (5)$$

moves with constant velocity P/M through space, where $M = m_1 + m_2$ is the total mass of the two-body system.

On the other hand, subtracting (2a) from (2b) gives

$$m d^2r/dt^2 = -Gm_1m_2r/r^3, \quad (6)$$

where $r = x_2 - x_1$, $r = |r|$, $M = m_1 + m_2$ as before, and $m = m_1m_2/(m_1 + m_2)$ is called the reduced mass. Equation (5) tells us that the problem of the relative motion of the two particles is equivalent to solving for the motion of a single (fictitious) particle of mass m in the same field of force centered at the origin of coordinates. Such a fixed force field pointing toward a given point in space (here chosen as the origin of coordinates) is called a central force.

Once (6) is solved, the original positions of the two gravitationally attracting particles may be reconstructed from the formulae

$$x_1 = R - m_2r/M, \quad x_2 = R + m_1r/M. \quad (7)$$

The differential equation for the vector function r is nonlinear because the magnitude of the force falls off with the square of the distance. Many force laws of interest in applications have the property that they are nonlinear functions of the positions of the constituent particles of the system. The force law for small extensions of a high-quality spring, known as Hooke's law, which states that the force is directly proportional to the deviation from equilibrium, is an important and notable exception.

Newton showed in the *Principia* that the general solution of (6) is that r traces out a conic section (ellipse or hyperbola, with a parabola as the "cross-over" possibility) corresponding to bounded or unbounded relative motions of the two original particles. The bounded motions apply to planets orbiting the Sun or the Moon orbiting the Earth. The effects of bodies farther away are to be treated subsequently by adding perturbations to the above analysis. Unbounded motions are realized by comets. Newton further considered the effects of the finite extension of the attracting body, for example, Earth's finite size relative to the Moon's orbit, and the effect of the deformation of the attracting body due to tidal forces.

NONEQUILIBRIUM STATISTICAL MECHANICS

Nonequilibrium statistical mechanics aims to describe the behavior of large systems of particles removed from the state of thermodynamic equilibrium, in terms of the properties of the individual constituents and their interactions, as provided by the laws of classical and quantum mechanics. Such systems give rise to irreversible behavior in the form of an approach to thermodynamic equilibrium in the absence of permanent constraints (isolated systems), or to

a stationary nonequilibrium state in systems under constraint (referred to as thermostatted systems).

The fundamental problem of non-equilibrium statistical mechanics is to reconcile irreversible behavior at the macroscopic level with the reversible character of the underlying microscopic laws of mechanics. For a long time it was thought that irreversibility could not be understood entirely from mechanics, an idea that led to the systematic introduction of probabilistic ideas in the traditional deterministic description. As a result, the laws of statistical mechanics have frequently been regarded as analogs of the law of large numbers and similar universal laws of probability and statistics, independent of any explicit reference to the nature of the underlying dynamics. Since the 1980s, one has witnessed a change of perspective following the realization that the trajectories of individual particles in an N -body system are typically chaotic.

Boltzmann's Kinetic Theory. Ergodic and Mixing Hypotheses

In 1872, Ludwig Boltzmann derived by what appeared to be completely mechanical arguments his famous kinetic equation for dilute gases (Brush, 1965, 1966). This equation features the time-dependent probability distribution function f , of position $\mathbf{r}$ and velocity $\mathbf{v}$, for a particle in the gas and allows one to reproduce in a very satisfactory way the transport and flow properties of the system. The kinetic theory culminates in the derivation of the H-theorem, whereby in a homogeneous system the functional $H = k \int f \ln f \, d\mathbf{v}$ (k being the Boltzmann constant) decreases monotonously until f reaches its equilibrium form given by the Maxwell-Boltzmann distribution. The H-theorem should provide, then, a microscopic justification of the second law of thermodynamics. This claim prompted rather negative reactions, crystallized in the famous reversibility (Loschmidt's) and recurrence (Zermelo's) paradoxes. Boltzmann was unable to fully refute these objections since, as he himself recognized, his derivation makes use of a heuristic probabilistic assumption—the *Stosszahlansatz* or the assumption of molecular chaos—which allowed him to express approximately the rate at which binary collisions are taking place only in terms of the one-particle probability density f .

In trying to answer his critics Boltzmann enunciated the ergodic hypothesis, which eventually became a key concept in the entire field of statistical mechanics. Specifically, Boltzmann suggested that (a) in an isolated many-body system the overwhelming part of the phase space consists of regions where the macroscopic properties are very close to the equilibrium properties, (b) the system's trajectory will spend equal times in phase space regions of equal extent, and (c) the macroscopic properties of the system will essentially

be constant throughout the allowable part of phase space and will coincide with the long-time averages of the corresponding microscopic quantities over the phase space trajectory. These statements were later completed by the equally ground-breaking discovery by Josiah W. Gibbs of the concept of mixing: the dynamical evolution of an isolated system initially occupying a limited phase space region compatible with some prescribed values of its macroscopic observables will lead it eventually to occupy uniformly (at least in a coarse-grained sense) the entire phase space available.

In their original forms, the ergodic hypothesis and the stronger mixing hypothesis had the serious drawback of relying to a considerable extent on the coarse-grained way one observes the system. Modern ergodic theory starts with the work of Henri Poincaré and George Birkhoff (Amol'd & Avez, 1968), who were able to relate ergodicity to certain well-defined properties of the underlying deterministic evolution laws. Two examples are provided by Birkhoff's theorem on the existence of the limit $1/T \int_0^T A(t) \, dt$ as $T \rightarrow \infty$ of an integrable phase space function A provided that the motion remains bounded in phase space and by Poincaré's theorem that for systems satisfying suitable resonance conditions there exist no invariants other than total energy that are analytic in some parameter. Since the 1950s, a great deal of effort has been devoted to prove whether a system described by a given Hamiltonian will or will not fulfill these properties and to what extent these properties bear a clear-cut relationship with the type of dynamics going on in phase space. An early (negative) result of considerable historical importance was obtained by Enrico Fermi, John R. Pasta, and Stanislaw Ulam (1955), who showed that in a system of coupled nonlinear oscillators energy may remain localized rather than be equipartitioned among the individual degrees of freedom. At the other extreme, one finds Yakov Sinai's result (Sinai, 1970) on the ergodic and mixing behavior of a system of hard spheres. This work signaled the beginning of a series of developments aimed at relating the foundations of non-equilibrium statistical mechanics to the instability of motion of large classes of non-integrable dynamical systems giving rise to sensitivity to initial conditions and to deterministic chaos, known to be generic since the work of Andrei Kolmogorov.

Generalized Kinetic Theories

In parallel, and largely independently of progress in ergodic theory, the need to go beyond the assumptions underlying Boltzmann's equation became a central preoccupation from the mid-1940s. Three major attempts along this line were initiated by Nikolai Bogolubov, Leon Van Hove, and Ilya Prigogine and his colleagues (see, e.g., Balescu, 1975). Their

starting point was a systematic perturbation expansion of the Liouville equation and its quantum counterpart for the N -particle probability distribution or density matrix, or the hierarchy of equations for the reduced n -particle ($n = 1, \dots, N$) distribution functions obtained by integrating the Liouville equation over the $N - n$ particles, known as the BBGKY hierarchy. This procedure led as a first step to exact, formal non-Markovian equations of the form

$$\frac{\partial \rho_s}{\partial t} + K \rho_s(t) = \int_0^t d\tau G(t - \tau) \rho_s(\tau) + D(t), \quad (1)$$

where ρ_s is a reduced distribution, K stands for the contribution of the mean field, G is a memory kernel, and $D(t)$ depends on the initial correlations in the sub-space of phase space complementary to the one of ρ_s . Closed kinetic equations for reduced probability densities could then be obtained under certain assumptions, linked to first principles in a more clear-cut way than Boltzmann's *Stosszahlansatz*: Bogolubov's ansatz of higher-order distributions becoming functionals of the one-particle one, Prigogine's ansatz on initial correlations, van Hove's random phase approximation. But even when these conditions are satisfied, it has so far proved impossible to establish a general H-theorem for the corresponding equations. Still, generalized kinetic equations have been at the foundation of spectacular progress in such fields as the study of dense fluids and plasmas and the microscopic theory of transport coefficients in the linear range of irreversible phenomena close to equilibrium.

Microscopic Chaos and Nonequilibrium Statistic Mechanics

Generalized kinetic theories rest on approximations whose validity is difficult to assess. Furthermore, there is no explicit link between the structure of the kinetic equations and the nature of the microscopic dynamics in phase space. In view of the fundamental importance and the ubiquity of irreversibility in the natural world, it would certainly be desirable to arrive at a description free of both these limitations. This has been achieved since the 1980s by the cross-fertilization between dynamical systems, non-equilibrium statistical mechanics, and microscopic simulation techniques.

Mapping to a Markov Process

A first series of attempts pertains to the class of strongly unstable systems known as Kolmogorov flows, in which each phase space point lies at the intersection of stable and unstable manifolds. It takes advantage of the existence in such systems of special phase space partitions—the Markov partitions—whose boundaries remain invariant under the dynamics, each partition cell being mapped at successive time steps into a union

of partition cells. If the operator projecting the full phase space dynamics on such a partition commutes with the Liouville operator, then the Liouville equation can be mapped into an exact Markovian equation exhibiting an H-theorem. This provides a rigorous microscopic basis of coarse-graining (Penrose, 1970; Nicolis et al., 1991). The mapping is, however, not one-to-one as the projection operator is not invertible reflecting the loss of information associated with this process. Ilya Prigogine, Baidyanath Misra, and Maurice Courbage (Prigogine, 1980) succeeded in constructing a non-unitary, invertible, transformation operator Λ , which transforms the unitary evolution operator U_t (essentially the exponential of the Liouville operator) into a Markov semigroup W_t

$$W_t = \Lambda U_t \Lambda^{-1} \quad (2)$$

The idea of non-unitary transformations has also been extended to more general classes of systems, such as non-integrable systems generating Poincaré resonances.

Escape Rate Formalism and Deterministic Thermostats

A second line of approach aims to express transport coefficients and other macroscopic level properties including entropy production in terms of the quantifiers of the microscopic chaos prevailing at the level of individual particle trajectories (in a classical setting). Two different methodologies have been developed.

The escape rate formalism (Gaspard, 1998; Dorfman, 1999). In this formalism, transport in Lorentz gas type systems is linked to the escape from a fractal repeller formed by trajectories for which a certain microscopic quantity associated with the macroscopic flux of interest remains confined in phase space. The corresponding transport coefficients are then expressed in terms of the Lyapunov exponents of the repeller and its Kolmogorov–Sinai entropy or its fractal dimension. No boundary conditions need to be imposed. Furthermore, the hydrodynamic modes associated with the process are computed as generalized eigenmodes of the Liouvillean and turn out to be fractal distributions.

Deterministic thermostats. The question here is how to express in purely mechanical terms a constraint maintaining a system away from equilibrium. One of the most popular ways to achieve this is to augment (in a classical system) the Hamiltonian dynamics by dynamical friction terms preserving the time-reversal symmetry (Hoover, 1999). In this way, one obtains a dissipative dynamical system where the rate of phase space volume contraction and the entropy production are shown to be related to the sum of the Lyapunov exponents. The non-equilibrium steady states generated in this formalism are fractal attractors, contrary to the equilibrium states that extend over the entire phase space available. Furthermore, they are believed to satisfy an interesting fluctuation theorem (Gallavotti &

Cohen, 1995) expressing the probability of fluctuations associated with particles moving in a direction opposite to the applied constraint.

Statistical Mechanics of Dynamical Systems

Yakov Sinai, David Ruelle, and Rufus Bowen (see, for example, Ruelle, 1999) have shown that the long-time behavior of a large class of chaotic dynamical systems is determined by an invariant probability measure characterized by a variational principle, thereby establishing a link with ergodic theory and equilibrium statistical mechanics. A major difference is that contrary to equilibrium measures, Sinai–Ruelle–Bowen (SRB) measures are smooth only along the expanding directions while they possess a fractal structure along the contracting ones. This provides a rationale for characterizing the fractal character of the non-equilibrium steady states generated by deterministic thermostats. Furthermore, it has been the starting point of a series of developments aimed at characterizing low-order deterministic dynamical systems showing complex behavior through probability densities and the spectral properties of their evolution operators, such as the Liouville or the Frobenius–Perron operators (Lasota & Mackey, 1985). In a different vein, the transport induced by the overlap of resonances arising, in particular, around a separatrix has been investigated (Lichtenberg & Lieberman, 1983; Balescu, 1997). These approaches have provided insights to questions motivated by non-equilibrium statistical mechanics that had remained unsolved for a long time, owing to the formidable difficulties arising from the presence of a large number of interacting particles.

Non-equilibrium Statistical Mechanics as a Tool to Understand Cooperative Behavior in Complex Systems

Non-equilibrium statistical mechanics has been a source of inspiration providing interesting ways to analyze complex nonlinear systems arising in chemistry, fluid mechanics, biology, or even finance and sociology. One of the earliest applications was a mesoscopic approach describing the dynamics of fluctuations of the macroscopic observables of such systems around a reference state, using master equation or Langevin–Fokker–Planck equation descriptions (Nicolis & Prigogine, 1977; Haken, 1977). It led to a theory of nonequilibrium phase transitions showing how macroscopic level bifurcation phenomena are reflected at the microscopic level through the anomalous behavior of the non-equilibrium fluctuations. When applied to nanoscale systems, this approach provides interesting insights on energy transduction by non-equilibrium devices such as biological macromolecules, referred to as molecular motors (Astumian, 1997).

Finally, the formalism of non-equilibrium statistical mechanics is well suited to studying the cooperative behavior of interacting multi-agent systems involved in, for instance, food webs and other networks of connected elements, finance, or social phenomena. In this setting, the relevance of power laws describing the statistical behavior of certain systems has attracted considerable interest, the idea being that such laws reflect well the ability of complex systems to show adaptive behavior and to optimize information flows (Albert & Barabasi, 2002). The dynamical origin of these laws and the role of non-equilibrium constraints remain major open questions.

NONLINEAR ACOUSTICS

As an area of physics and mechanics concerned with sound waves of finite amplitude, theoretical nonlinear acoustics stems from advances in classical fluid mechanics made in the 19th century. It was developed originally as a weakly nonlinear limit of gas dynamics and included the study of simple waves, weak shock waves, and their interactions. Nonlinear acoustics as a separate branch of science was formed mainly during and after World War II when, on the one hand, military applications of underwater acoustics became important, and on the other, more powerful sources of sound were developed.

The nature of finite-amplitude acoustic wave propagation in fluids depends on the value of the acoustic Reynolds number $Re = \beta u_0 \lambda / \nu$, where u_0 is a characteristic amplitude of the particle velocity, λ is the wavelength, ν the kinematic viscosity (or a combination of viscosity and thermal conductivity), and β is the coefficient of nonlinearity (1.2 for air, 3.5 for water). For $Re \leq 1$, the wave attenuates before significant nonlinear distortion accumulates. For $Re \gg 1$, higher harmonics are generated, and the wave profile may undergo radical changes.

The physical process underlying waveform distortion for a plane (one-dimensional) traveling wave is the simple-wave characteristic relation $dx/dt = c_0 + \beta u$ for the propagation speed of individual points on the waveform, where c_0 is the small-signal (infinitesimal-amplitude) sound speed. Positive values of the particle velocity u (or sound pressure) in the waveform advance on the zero crossings propagating at speed c_0 , and negative values recede. For $Re \gg 1$, this process leads to waveform steepening up to the “breaking” point, beyond which this propagation law predicts a multivalued waveform (see Figure 1). Whereas water waves break, sound waves cannot, and instead an abrupt jump in the wave amplitude, referred to as a shock front, is formed. Shocks substantially increase attenuation of the wave, and their thickness is proportional to a combination of viscosity and thermal conductivity coefficients.

The process just discussed is well described by a plane traveling wave by the Burgers equation

$$\frac{\partial u}{\partial t} + (c_0 + \beta u) \frac{\partial u}{\partial x} = \delta \frac{\partial^2 u}{\partial x^2}, \quad (1)$$

Figure 1. Schematic of the evolution of an initially sinusoidal nonlinear acoustic wave. Each plot corresponds to the one-period waveform as a function of coordinate at the successive time moments.

where δ is a dissipation coefficient that accounts for viscosity and thermal conductivity and equals $2\nu/3$ for shear viscosity alone. The left-hand side accounts for the finite-amplitude propagation speed given above. The Reynolds number, given above, characterizes the ratio of the nonlinear term to the dissipation term. Equation (1) is expressed in a form convenient for initial value problems, when an initial spatial waveform is prescribed. An alternative form of Equation (1), with the roles of x and t reversed, is used in signaling problems, in which a time waveform is prescribed on a boundary. Similar processes occur in spherical waves, such as those at sufficient distances from explosions, where the nonlinearity is weak.

An important role in the development of modern nonlinear acoustics has been played by the parametric array conceived by Westervelt in the USA and Zverev and Kalachev in Russia in the early 1960s. In the parametric array, two acoustic beams close in frequency interact nonlinearly and create a virtual antenna that radiates a secondary, low-frequency beam. Notwithstanding their low efficiency, these antennas prove useful in applications (such as sea bottom profiling) because of their high directivity and absence of side lobes.

Describing the parametric array and nonlinear sound beams, in general, is a complicated problem that requires taking into account the effect of diffraction. The combined effects of nonlinearity, attenuation, and diffraction on a sound beam may be modeled with an augmented form of Equation (1) called the Khokhlov–Zabolotskaya–Kuznetsov (KZK) equation. This equation contains an additional term that accounts for the diffraction of narrow beams. It is widely used for calculations of finite-amplitude sonars, such as the parametric array, and focused beams of high-intensity ultrasound used in imaging and medicine. Further augmentation of Equation (1) permits investigation of nonlinear propagation in inhomogeneous media

and leads to a theoretical formalism called "nonlinear geometrical acoustics," which is used to study the evolution of ray patterns.

Acoustic fields in fluids can also generate time-averaged effects such as acoustic streaming (steady flow) and radiation pressure. Acoustic streaming provides a basis for some microfluidic pumps, and in other applications, it influences heat transfer. Radiation pressures generated by standing waves are used to levitate and manipulate particles and bubbles, especially in microgravity environments. Accurate prediction of these time-averaged effects requires special care when defining the problem under consideration.

Nonlinear acoustics of solids includes a variety of interactions between different wave types, such as longitudinal, shear, and surface waves in isotropic solids. Additional types of wave interactions occur in anisotropic media (crystals). The different propagation speeds of the various waves lead to selection rules for particular wave interactions, usually connected with the direction of propagation. Surface (interface) waves exhibit nonlinear propagation effects that differ fundamentally from those of bulk longitudinal and shear waves. Their penetration depth away from an interface is proportional to wavelength, and this frequency-dependent property gives rise to nonlocal nonlinearity that does not occur in bulk waves. With nonlocal nonlinearity, the nonlinear perturbation of the wave velocity at any given point on a waveform is influenced by the entire wave field.

Along with "classical" homogeneous media in which the nonlinearity is due to anharmonicity of atomic forces, there exists an important class of "structurally" nonlinear media in which the nonlinearity is due to the presence of soft inclusions in a harder main body. Examples are small gas bubbles in liquids, pores in rubber-like materials, and grain contacts, microcracks, and dislocations in solids. Acoustic nonlinearities in such media can be several orders stronger than in homogeneous media. Moreover, the nonlinear equation of state (stress-strain relation) in such materials as metals and rock can predict irreversible behavior (hysteresis), which results in some unusual effects; for example, the third-harmonic amplitude in a strain wave can be proportional to the square of the primary-wave amplitude, rather than to its cube.

From a physical viewpoint, classical nonlinear acoustics deals mainly with non- or weakly-dispersive media, in which cumulative waveform steepening and harmonic generation occurs until shocks are formed. Dispersion in acoustics can be introduced by waveguide walls (geometrical dispersion) or by inhomogeneities such as grains and bubbles. As a result, many effects known in nonlinear optics and plasma physics have been realized in acoustics, such as self-focusing, phase conjugation (wave front reversal), and parametric amplification. Acoustic solitons, in which certain effects

of nonlinearity and dispersion offset each another, are also possible. Even an acoustical analog of the maser, in which randomly phased oscillators (such as resonant bubbles) self-synchronize and radiate coherently, is possible.

Applications and manifestations of nonlinear acoustics are numerous. Besides the aforementioned processes, acoustic nonlinearities are important in explosion waves, sonic booms, thermoacoustic engines (in which sound waves serve as heat pumps), therapeutic and diagnostic medical ultrasound, materials characterization, and nondestructive testing. Shock waves also form inside collapsing cavitation bubbles, and they are thought to influence the resulting flashes of light referred to as sonoluminescence.

NONLINEAR ELECTRONICS

In the early part of the 20th century, vacuum tube devices dominated electronics circuitry. However with the advent of junction transistors in 1951 and integrated chips in 1957, semiconductor devices largely replaced vacuum tubes by the 1970s. Present-day electronic circuits make extensive use of active elements/devices that may behave either linearly or nonlinearly, depending upon their applications, operating currents, and voltages (as well as various physical effects including thermal effects, dielectric breakdown, and magnetic saturation). Typical modern nonlinear devices include semiconductor diodes, bipolar junction transistors (BJTs), and field effect transistors (FETs). For analysis and design, the nonlinear devices are often replaced by equivalent basic nonlinear circuit elements such as two-terminal, multiterminal, and multiport resistors, capacitors, and inductors. Thus, a nonlinear electronic circuit is an interconnection of the various circuit elements involving at least one nonlinear element.

The major nonlinear two-terminal circuit elements are typically characterized by nonlinear functional representations in contrast to their linear counterparts: (i) nonlinear resistor: nonlinear voltage $v(t)$ vs.

Figure 1. (a) Linear resistor and its $v-i$ characteristic (b) Nonlinear resistor and its $v-i$ characteristic.

current $i(t)$ characteristic curve, (ii) nonlinear capacitor: nonlinear charge $q(t)$ vs. voltage $v(t)$ curve, and (iii) nonlinear inductor: nonlinear $i(t)$ vs. magnetic flux $\Phi(t)$ curve (for an illustrative example, see Figure 1). More general circuit elements, such as three terminal transistors and multipliers, and multiterminal elements, such as operational amplifiers (opamps), are also frequently used (Chua et al., 1987; Schubert & Kim, 1996). An innovative nonlinear element is the piecewise-linear device, namely Chua's diode synthesized using opamps/diodes and linear elements (possessing a five-segment $v-i$ characteristic curve, including three negative resistance pieces, see Figure 2), which plays a crucial role in understanding various nonlinear dynamical phenomena (Lakshmanan & Murali, 1996; Lakshmanan & Rajasekar, 2003). The state equations for the currents and voltages underlying a given nonlinear electronic circuit, which are deduced using Kirchhoff's laws for electrical circuits, turn out to be a system of coupled nonlinear differential equations. In particular, when a given circuit includes at least two energy storage elements such as capacitors and inductors and a nonlinear element (which can typically function as an amplifier), it behaves as an oscillator for appropriate feedback and circuit parameters. The underlying system of nonlinear differential equations can then be equivalently considered as a typical nonlinear oscillator dynamical system of dissipative type.

Historically, the relaxation oscillator investigated by the Dutch engineer Balthasar der Pol in his seminal paper, "Frequency Demultiplication" (van der Pol & van der Mark, 1927), may be considered as the earliest example of a nonlinear electronic circuit, exhibiting many of the characteristic features underlying bifurcations and chaos, though not fully understood at that time. The circuit typically consists of a high voltage dc source E attached via a large series

Figure 2. (a) Chua's diode and (b) its characteristic.

Figure 3. Van der Pol's original oscillator circuit.

resistance R to a neon bulb N_R (or a triode valve) and a capacitor C , which are connected in parallel (see Figure 3) along with an external periodic signal V_S . As the capacitance C is increased smoothly, the current exhibits "discrete jumps from one whole-submultiple of the driving frequency to the next." For a critical value of the amplitude of the driving signal, this pattern of mode-lockings has a self-similar fractal structure consisting of an infinite number of steps. In modern jargon, this is just the devil's staircase (Kennedy & Chua, 1986). Van der Pol also noted that "often an irregular noise is heard in the telephone receiver [monitoring the signal in some way] before the frequency jumps to the next level value." Now we know that this "noise" indeed corresponds to chaotic signals. Typically, the circuit is represented by the second-order non-autonomous nonlinear differential equation

$$\frac{d^2x}{dt^2} + \varepsilon (x^2 - 1) \frac{dx}{dt} + x = f \sin \omega t, \quad (1)$$

where ε is the damping coefficient and f and ω represent the strength and frequency, respectively, of the periodic external forcing.

Figure 4. MLC Circuit: N is Chua's diode and $f(t)$ is the periodic signal.

Similar circuits are useful for modeling physical and biological systems; examples include flow of current across Josephson junctions or nerve impulse propagation in neuronal fiber in the form of Hodgkin–Huxley or FitzHugh–Nagumo equations (Scott, 2003). From the point of view of nonlinear dynamics, nonlinear electronic circuits arise either in analog simulation of typical nonlinear oscillators such as the Duffing oscillator or Lorenz system or as new dynamical systems per se constructed using typical nonlinear devices or ingeniously designed elements such as Chua's diode to act as black boxes to understand the various novel nonlinear phenomena. Examples of the latter include Chua's circuit/oscillator and Murali–Lakshmanan–Chua (MLC) circuit (Figure 4). In either case, these circuits are easy to build, analyse, and model, and help to scan the control parameter space quickly, thereby complementing numerical and analytical studies of nonlinear phenomena.

Just like standard nonlinear dissipative dynamical systems, nonlinear electronic circuits typically exhibit various dynamical phenomena including bifurcations and chaos (Lakshmanan & Murali, 1996; Lakshmanan & Rajasekar, 2003; Thompson & Stewart, 1986).

- **Multistable states:** These correspond to point attractors (nodes and spiral points) as exhibited, for example, by any flip-flop or Schmitt trigger.
- **Periodic oscillations:** Autonomous nonlinear circuits can typically exhibit sinusoidal time response for weak nonlinearity (e.g., LC oscillators) and nearly square wave response (relaxation oscillators) for strong nonlinearity (e.g., square wave generators, Schmitt triggers). On the other hand, non-autonomous circuits often exhibit nonlinear resonant (harmonic, subharmonic, superharmonic, and dissipative) oscillations for weak nonlinearity (e.g., ferroresonant circuit with ac voltage source, hysteresis circuits, power amplifiers).
- **Bifurcations and chaos:** Almost the entire spectrum of bifurcations and chaos phenomena encountered in typical chaotic nonlinear dynamical systems is exhibited by numerous simple nonlinear electronic circuits/oscillators (e.g., Duffing oscillator, van der

Pol oscillator, Chua's circuit, MLC circuit, RL diode circuit, Colpitts oscillator, Buck converters in power electronics).

- **Synchronization and controlling:** Nonlinear electronic circuits are versatile models to study and understand the phenomenon of synchronization in all its manifestations (such as identical, phase, lag, and generalized synchronizations) both with periodic and chaotic oscillations between two or a chain of oscillators. Similarly, to study various controlling techniques of periodic as well as chaotic oscillations, nonlinear circuits play a crucial role.
- **Secure communications and cryptography:** Because of the inherent advantage of miniaturization, nonlinear electronic circuits are natural choices for chaos application studies in secure communications, cryptography, and signal processing.

Nonlinear electronic circuits have become indispensable tools to understand a multitude of nonlinear dynamical phenomena, including chaos. In turn, nonlinear electronics has itself been enriched greatly by the advances in understanding various complex nonlinear phenomena, leading to the potential applications mentioned above.

NONLINEAR OPTICS

Maxwell's theory of electrical and magnetic fields and his idea that light is an electromagnetic wave were among the great milestones of scientific thought, unifying our understanding of a large and diversified range of physical phenomena. Indeed, by the late 19th century, the success of the classical electromagnetic theory of light led some to believe

that there were few fundamental discoveries to be made.

Nonlinear properties of Maxwell's constitutive relations $\mathbf{B} = \mu(\mathbf{H})\mathbf{H}$, $\mathbf{D} = \epsilon(\mathbf{E})\mathbf{E}$ had been recognized from the beginning. For example, the nonlinear permeability of ferromagnetic media was of prime concern in the design of electrical machinery in the 19th century. Nonlinear properties in the optical region had to await the discovery of the ruby laser in 1960 by Theodore Maiman (Maiman, 1960). The defining experiment by Peter Franken and coworkers in 1961 (Franken et al., 1961) detected ultraviolet light ($\lambda = 3470\text{\AA}$) at twice the frequency of a ruby laser ($\lambda = 6940\text{\AA}$) when this beam traversed a quartz crystal. (There is a humorous story about this discovery: the detected radiation was so weak that it appeared as a very faint spot on the photograph submitted to *Physical Review Letters*. The typesetting staff assumed that it was a glitch and erased it in the published document!) This experiment spurred a flurry of activity and many nonlinear optical phenomena were rapidly discovered. A series of monographs by Nicolaas Bloembergen in the 1960s (see Bloembergen, 1996a,b) contain an excellent historical overview of the explosive growth of activity in this field in the early days (see also Marburger, 1977; Shen, 1977).

For the most part, the study of nonlinear optical phenomena assumes a quantum material system coupled to a classical electromagnetic field. Within this approximation, noise-driven phenomena can be adequately described by a Langevin-type driving force. A proper description of quantum effects such as spontaneous emission or scattering requires that the electromagnetic field itself be quantized. Most nonlinear optical materials are nonmagnetic, so one sets the magnetic permeability $\mu(\mathbf{H}) = \mu_0$, a constant. The procedure then is to expand the dielectric permeability $\epsilon(\mathbf{E})$ as a formal power series in the electric field. This is most commonly done by defining an induced polarization field in terms of the electric displacement vector $\mathbf{D} = \epsilon_0\mathbf{E} + \mathbf{P}$, where $\mathbf{P} = \mathbf{P}_L + \mathbf{P}_{NL}$ (linear and nonlinear contributions). The first term on the right-hand side of the expression for the electric displacement vector $\mathbf{D}$ is the vacuum contribution. The polarization $\mathbf{P}$ describes the coupling of the light to induced dipoles in the material, and this physical quantity is expanded in series in powers of the electric field, $\mathbf{E}$, as follows.

$$\begin{aligned} \frac{1}{\epsilon_0}\mathbf{P} = & \int \bar{\bar{\chi}}_1(\tau) \mathbf{E}(t - \tau) d\tau \\ & + \int \int \bar{\bar{\chi}}_2(\tau_1, \tau_2) \mathbf{E}(t - \tau_1) \\ & \times \mathbf{E}(t - \tau_2) d\tau_1 d\tau_2 \\ & + \int \int \int \bar{\bar{\chi}}_3(\tau_1, \tau_2, \tau_3) \mathbf{E}(t - \tau_1) \end{aligned}$$

$$\begin{aligned} & \times \mathbf{E}(t - \tau_2) \mathbf{E}(t - \tau_3) d\tau_1 d\tau_2 d\tau_3 + \dots \\ = & \frac{1}{2\pi} \int \bar{\bar{\chi}}_1(\omega) \tilde{\mathbf{E}}(\omega) e^{-i\omega t} d\omega \\ & + \frac{1}{(2\pi)^2} \int \int \bar{\bar{\chi}}_2(\omega_1, \omega_2) \\ & \times \tilde{\mathbf{E}}(\omega_1) \tilde{\mathbf{E}}(\omega_2) e^{-i(\omega_1 + \omega_2)t} d\omega_1 d\omega_2 \\ & + \frac{1}{(2\pi)^3} \int \int \int \bar{\bar{\chi}}_3(\omega_1, \omega_2, \omega_3) \tilde{\mathbf{E}}(\omega_1) \tilde{\mathbf{E}}(\omega_2) \\ & \times \tilde{\mathbf{E}}(\omega_3) e^{-i(\omega_1 + \omega_2 + \omega_3)t} d\omega_1 d\omega_2 d\omega_3 + \dots \end{aligned} \quad (1)$$

Here, the dielectric susceptibility terms $\bar{\bar{\chi}}_j$, $j = 1, 2, 3$ are second, third, and fourth rank tensors, respectively. The latter are causal functions and tensor product notation is assumed. The second equality is written in terms of Fourier transform variables. Although, in principle, the dielectric susceptibilities at each order could be obtained from fully ab initio quantum mechanical calculations on the relevant materials, in practice, such calculations are too complex and one usually has to rely on experimentally measured data. Higher order processes than those displayed explicitly in this equation are generally unimportant because the leading order accessible nonlinear effect dominates. (Exceptions occur when nonlinear saturation becomes important.) The above induced polarization term acts as a source for the electromagnetic field in Maxwell's vector wave equation,

$$\frac{\partial^2 \mathbf{E}}{\partial t^2} - \frac{1}{c^2} \frac{\partial^2 \mathbf{E}}{\partial z^2} - \nabla \cdot (\nabla \cdot \mathbf{E}) = \frac{1}{\mu_0} \frac{\partial^2 \mathbf{P}}{\partial t^2}. \quad (2)$$

The leading order term $\bar{\bar{\chi}}_1$ above is a second rank tensor that describes all linear optical interactions involving propagating optical fields of any arbitrary polarization. For virtually all nonlinear optical interactions, it is appropriate to expand the electric field vector as a linear combination of products of envelope functions and optical carrier waves

$$\begin{aligned} \mathbf{E}(\mathbf{r}, t) = & \sum_j \hat{\mathbf{e}}_j A_j(\mathbf{r}, t) \exp(i(\pm \mathbf{k}_j \cdot \mathbf{r} - \omega_j t)) \\ & + \text{c.c.} \end{aligned} \quad (3)$$

Here A_j are slowly varying envelope functions, and $\hat{\mathbf{e}}_j$ is a unit vector indicating the direction of polarization. Each wave vector or frequency pair $(\mathbf{k}_j, \omega_j)$ satisfies a linear dispersion relation $D(\mathbf{k}_j, \omega_j) = 0$. A goal in nonlinear optics is to write down evolution equations for the complex slowly varying envelope functions A_j . The structure of these equations, which describe how almost monochromatic, weakly nonlinear, dispersive wave trains interact, is universal and so many of the properties of lightwaves

can be inferred from corresponding situations in other fields.

The leading nonlinear behavior in noncentrosymmetric crystals is due to the second order term $\overline{\chi}_2$, a third rank tensor (with 9 components). This term is responsible for second harmonic generation as first observed by Franken et al. (1961). Significant quadratic nonlinear interactions between wave packets take place when triads of wave vectors and frequencies $\mathbf{k}_j, \omega_j$ obey

$$\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3 = 0, \quad \omega_1 \pm \omega_2 \pm \omega_3 = 0, \quad (4)$$

where each $\mathbf{k}_j, \omega_j$ pair satisfies its own dispersion relation. Physical effects arising from this term include second harmonic generation ($2\omega_1 \rightarrow \omega_3$), dc rectification ($\omega_1 - \omega_1 \rightarrow 0$), and frequency up- and down-conversion ($\omega_1 \pm \omega_2 \rightarrow \omega_3$). The first two nonlinear interactions are termed degenerate because $\omega_1 = \omega_2$ and two photons ($2\hbar\omega_1$) in the incident laser beam are needed to create one second harmonic photon. For these three-wave interaction processes to be efficient both energy (i.e., $\hbar\omega_1 \pm \hbar\omega_2 = \hbar\omega_3$ for up-, down-conversion, $2\hbar\omega_1 = \hbar\omega_3$ for second harmonic generation) and momentum ($\hbar\mathbf{k}_1(\omega) \pm \hbar\mathbf{k}_2(\omega) = \hbar\mathbf{k}_3(\omega)$, for up-, down-conversion, $2\hbar\mathbf{k}_1(\omega) = \hbar\mathbf{k}_3(\omega)$ for harmonic generation) must be nearly conserved. (Here $\hbar\mathbf{k}$ is the photon momentum.) Three-wave interactions are generally difficult to observe in isotropic media as material dispersion precludes being able to satisfy the momentum conservation relation. A symmetry argument also shows that χ^2 -processes are forbidden in materials possessing a center of symmetry. Noncentrosymmetric uniaxial and biaxial crystals (those in which the refractive index is different in different directions in the crystal) are employed to achieve efficient phase matching. This is because the magnitude of the optical wave vector is related to the material refractive index through the relation $k = n(\omega)\omega/c$, where the dispersion of the refractive index $n(\omega)$ is explicitly displayed. The complex envelopes A_1, A_2 , and A_3 of the three wave packets obey the universal three-wave interaction equations of universal type

$$\frac{\partial A_j}{\partial t} + \mathbf{c}_j \cdot \nabla A_j = \theta_j A_l^* A_m^* \quad (5)$$

with j, l, m cycled over 1,2,3, where $\mathbf{c}_j$ is the linear group velocity of the j th wave packet and θ_j is a coupling coefficient proportional to $\overline{\chi}_2$.

Four-wave χ_3 -processes are the leading order nonlinear optical processes in a medium possessing a center of symmetry. Here significant exchange of energy only takes place between resonant quartets $(\mathbf{k}_j, \omega_j)_{j=1}^4$, each obeying its dispersion relation. Contrary to the triad resonance condition, energy conservation and phase matching can always be satisfied with several trivial choices. The nonlinear dielectric susceptibility is now a fourth rank tensor

although many of its components are either identical or zero, depending on crystal symmetry properties. Degenerate four-wave interactions include self-phase modulation (or Kerr effect, $\omega_1 + \omega_1 - \omega_1 \rightarrow \omega_1$) and third harmonic generation ($\omega_1 + \omega_1 + \omega_1 \rightarrow 3\omega_1$) (Terhune et al., 1962). Common nondegenerate third-order processes include four-wave-mixing (FWM) interactions.

Four-wave-mixing interactions can be used to create a "phase-conjugated wave." A nonlinear interference grating is created within the nonlinear material through the interaction of two strong pump waves satisfying $\mathbf{k}_1 + \mathbf{k}_2 = 0$ and $\omega_1 = \omega_2 = \omega$. A weak third wave scatters off this grating and generates a time-reversed phase-conjugated replica of itself. The incident and scattered waves satisfy $\mathbf{k}_3 + \mathbf{k}_4 = 0$ and $\omega_4 = \omega_3 = \omega$. FWM interactions can also lead to degradation in wavelength-division-multiplexed (WDM) long-haul fiber transmission systems as a result of energy transfer between equally spaced channels. Another important nondegenerate interaction involves the phenomenon of nonlinear birefringence where $\mathbf{k}_4, \omega_4 = -\mathbf{k}_2, -\omega_2$, $\mathbf{k}_3, \omega_3 = -\mathbf{k}_1, -\omega_1$ and the complex slowly varying functions A_1, A_2 represent envelope wave packets of different polarization direction. Coupled nonlinear Schrödinger (NLS) equations for the envelope fields $A_1(\mathbf{r}, t)$ and $A_2(\mathbf{r}, t)$ can be derived that describe nonlinear self- (i.e., $|A_1|^2 A_1$ in the A_1 equation and $|A_2|^2 A_2$ in the A_2 equation) and cross-phase modulation (i.e., $|A_2|^2 A_1$ in the A_1 equation and $|A_1|^2 A_2$ in the A_2 equation) for co- and counter-propagating laser pulses. The relative weighting of self- and cross-phase modulation nonlinearities depends on the material properties (Marburger, 1977) and plays an important role in polarization switching of soliton pulses in optical fibers. One can write down more general universal four-wave interaction equations along the lines described above for the three-wave interaction case.

A well-known degenerate χ_3 -process is the optical Kerr effect. This self-interaction term induces a nonlinear phase change proportional to the intensity $|A|^2$ of the propagating light pulse. This phase change, called self-phase modulation, is an accumulative propagation effect that is central to applications that exploit the optical Kerr effect. A canonical form of the D-dimensional NLS equation, incorporating the Kerr effect, can be written as follows:

$$i \left(\frac{\partial A}{\partial t} + \sum_{j=1}^D \left(\frac{\partial \omega}{\partial k_j} \right) \frac{\partial A}{\partial x_j} \right) - \sum_{j,l=1}^D \left(\frac{\partial^2 \omega}{\partial k_j \partial k_l} \right) \frac{\partial^2 A}{\partial x_j \partial x_l} + \left(\frac{\partial \omega}{\partial |A|^2} \right) |A|^2 A = 0. \quad (6)$$

The first two terms combined describe the advection of a pulse (wave packet) with group velocity $\mathbf{v}_g = \omega(\mathbf{k})$.

The second and third terms represent the balance between dispersion and weak nonlinearity. Higher order corrections terms can be derived as an asymptotic expansion in a small parameter as described in Newell & Moloney (1992). Dispersion in nonlinear optics is manifested in two physically distinct ways: diffraction describing spatial spreading of a tightly collimated beam or pulse in a direction transverse to the direction of propagation, and dispersive spreading in time (group velocity dispersion $\omega''(k)$) of an ultrashort laser pulse. The latter mechanism plays an increasingly influential role as the propagating laser pulse gets shorter and shorter.

In 1-d, the NLSE is integrable and the Kerr nonlinearity can balance group velocity dispersion to form temporal solitons in optical fibers. Both bright and dark temporal soliton pulses have been observed experimentally in fibers. Spatial soliton beams can be created in two-dimensional planar waveguides where there is strong confinement of the optical field in a single spatial dimension transverse to the propagation direction of the light beam. Spatial confinement in two (fibers) or one (planar waveguides) dimension is required to form stable soliton pulses or beams. In unconfined transparent bulk geometries, the optical Kerr effect is responsible for critical self-focusing, leading to extremely intense focused light that causes catastrophic damage in transparent glasses. Critical self-focusing was first observed experimentally by Chiao and coworkers in 1964 (Chiao et al., 1964).

There are other categories of nonlinear optical effects that can be described in terms of envelope functions and that depend sensitively on the finite response of some material oscillation. Stimulated scattering is a case in point. These processes are essentially three-wave interactions where one of the optical waves is replaced by a material oscillation. In transparent glasses for example, there are two characteristic modes of oscillation of the lattice as shown in Figure 1. The lower frequency acoustic phonon mode corresponds to an oscillation of all atoms in unison along a fixed direction in the lattice. The higher frequency optical phonon mode involves neighboring atoms in the lattice oscillating out of phase. The dispersion relation for lattice vibrations, therefore, contains an acoustic and optical branch, both of much lower frequency than the optical frequency.

Figure 1 shows a plot of the optical phonon (top curve) and acoustic phonon (bottom curve) dispersion for a diatomic crystal lattice within the first Brillouin zone. On the scale of this graph, the photon branch (light cone) is essentially vertical, making the acoustic and optical phonon dispersion essentially flat. An intense pump laser pulse at frequency ω_p entering a transparent glass can scatter off either a fluctuating low-frequency acoustic phonon (Stimulated Brillouin Scattering, SBS) or a fluctuating optical phonon (Stimulated

Figure 1. Acoustic (bottom) and optical (top) phonon branches of the dispersion curve for a diatomic lattice. The abscissa is scaled to the lattice constant "a."

Raman Scattering, SRS) at finite temperature. Energy conservation ensures that the scattered optical signal has a frequency $\omega_s = \omega_p - \omega_v$, where ω_v is the natural acoustic or optical phonon frequency. Technically, SBS and SRS processes look like a three-wave interaction where phase matching is easy as the dispersion of the material oscillation is locally flat on an optical frequency scale. In fact, it can be shown that these processes are essentially four-wave interactions, as the oscillator model, representing the material oscillation, is driven by the square of the optical field. Typically, SBS is generated in the backward direction and SRS can be generated in the forward and/or backward direction relative to the propagating pump laser pulse. SRS processes in liquids and gases can generate a cascade of frequency down-shifted (Stokes) and frequency up-shifted (anti-Stokes) waves. Although both SBS and SRS processes are essentially phase matched for all directions, they can only exist by feeding off the intense pump pulse. There also exists a degenerate stimulated scattering process called Stimulated Rayleigh Scattering—this is essentially a Kerr-like process with finite memory. All of these stimulated scattering phenomena can be observed in bulk transparent materials (Marburger, 1977; Shen, 1977) and optical fibers (Agrawal, 1989). They can be stimulated from noise or seeded at the optical signal wavelength by injecting a weak laser field.

Another important class of nonlinear optical phenomena involves direct resonant coupling to some form of material oscillation. The simplest physical manifestation of this category is the two-level atom. Absorbing/amplifying media that give rise to the phenomenon of self-induced transparency (SIT) and lasers belong to this category. The dielectric susceptibility is now complex with the real part corresponding to a refractive index change induced by the optical field and the imaginary part corresponding to absorption or amplification of light. The real and imaginary parts of the dielectric susceptibility are related through a Hilbert

transform—the Kramers–Kronig relation. Energy is directly transferred between optical fields and material oscillations. Self-induced transparency (SIT) solitons propagate when this coherent population or energy exchange can occur between the lower (L) and upper (U) level of a two-level atom on a timescale short relative to any irreversible energy decay processes such as spontaneous emission from the excited state (U). This population cycling between two levels occurs at a frequency $\omega_R = |\mu_{12}A|/\hbar$, where μ_{12} is the dipole matrix between the two levels and $\hbar$ is Planck's constant. The frequency ω_R is called the Rabi frequency, from the field of magnetic resonance spectroscopy. Figure 2a depicts this simple two-level atom scheme. For longer optical pulses, nonlinear saturation can occur in the presence of intense propagating optical fields. Population inversion, required for lasing action, cannot be achieved in a two-level atom (See **Lasers**). Optical amplification of light requires that a net inversion be achieved between the upper (U) and lower (L) atomic or molecular level involved in the light amplification process. Such inversion can be achieved by pumping atoms or molecules to energetically higher levels with a subsequent rapid non-radiative energy decay down to the upper excited level (U). Classical laser action can be described in terms of three-level and four-level quantum models. Figure 2b and c depict two classical lasing level schemes where the ground level population is pumped ($E = \hbar\omega_p$) into some upper excited state followed by a rapid (non-radiative) population decay (dashed arrows) to the upper excited level (U). The original ruby laser, discovered by Maiman in 1961, is an example of a three-level (actually three band) system schematically shown in Figure 2b. Inversion is more difficult to achieve in a three-level laser as the upper lasing level must have a net population in excess of that in the ground level. This requires pumping of more than half of the atoms to the upper lasing level. In the four-level laser, the lower lasing state is not the ground state and its initial population can be zero or very small due to finite temperature populations. Efficient lasing is achieved by rapidly removing the populations from the lower lasing level (L).

Such energy level schemes are generally gross simplifications of a real laser although they provide useful models of solid state and gas lasers (Siegman, 1986). Fiber lasers with erbium and/or ytterbium-doped cores belong to the category of solid state lasers. Semiconductor lasers, on the other hand, are extremely complex many-body systems involving many bands rather than levels and the above descriptions prove inadequate.

Key current developments in the field of nonlinear optics have benefited from technical developments that have enabled experimentalists to produce ultrashort laser pulses and invent novel materials processing methodologies. We sketch some of the key areas of research where such effects have been exploited in recent years.

Figure 2. (a). Two-level energy level scheme. (b). Three-level lasing level scheme. (c). Four-level lasing level scheme.

Nonlinear Optical Data Processing

A cumulative intensity-induced phase shift due to the Kerr nonlinearity, of the order of p , provides one of the most useful all-optical data processing capabilities. High-speed optical sampling, switching, amplification and storage applications abound, based on this nonlinear mechanism. Optical switching and data sampling can be implemented in directional couplers and Mach–Zehnder interferometers in both waveguide and fiber arrangements. Optical amplification and storage of pulse trains representing digital information can be achieved by placing a nonlinear transparent Kerr medium in a ring or Fabry–Perot cavity arrangement. So-called optical bistable elements require an injected holding beam to maintain the cavity at some threshold level whereby an incremental input can lead to strong amplification or storage of the system in one of two stable accessible states. The latter situation is depicted in Figure 3. Here the system has a memory (hysteresis) whereby a lower (bit 0) and upper (bit 1) state can be switched by some external perturbation. Adjusting some cavity parameter can also lead to a single-valued but rapidly rising output transmission of the system. This is useful for amplifying injected pulse streams.

Figure 3. Hysteresis loop for a bistable optical cavity.

Such passive optical bistable cavities have also been shown to exhibit deterministic chaotic dynamics when the finite time delay of the optical signal circulating in the optical resonator has been taken into account. When transverse degrees of freedom of the external pump laser beam are included, so-called transverse spatial solitons have been observed. Although technology applications have been envisioned for both of these dynamical phenomena, there are no specific implementations to date.

Chaotic Synchronization and Communication with Lasers

Semiconductor lasers are highly susceptible to exhibiting chaotic dynamics even in the presence of extremely weak (10^{-4}) feedback from an external reflecting surface. This tendency to readily exhibit deterministic chaos means that semiconductor laser sources require greater than 40 dB optical isolation, making them the most expensive component in an optical fiber telecommunications network. Research in recent years has focused on taking advantage of this chaos by demonstrating that chaotic transmitter and receiver lasers can be synchronized and messages encoded and decoded at the transmitter and receiver end, respectively. Mathematically, these chaotic lasers are described at the simplest level by delay differential equations.

Quasi-phase Matching in Isotropic Media

Quasi-phase matching (QPM) is a means of beating the usual triad resonance condition needed to efficiently transfer energy between waves in second harmonic generation. Figure 4 shows the ideal phase-matched energy transfer to second harmonic as a function of propagation distance in a uniaxial crystal. When detuned from the phase-matching condition, energy transfer occurs less efficiently and there is a periodic transfer back and forth between the fundamental at frequency and the second harmonic signal at frequency 2ω . In this case, one observes the oscillatory

Figure 4. Comparison of energy transfer from the fundamental to the second harmonic for phase-matched, detuned and quasi-phase-matched conditions.

nonphase-matched behavior depicted in the picture. This is typically the situation encountered in isotropic materials.

Quasi-phase matching entails taking a crystal with a nonlinear coefficient and periodically reverting the sign of the dipoles in such a way that the phase of the wave is reversed every coherence length along the crystal. The latter is proportional to the refractive index mismatch at the fundamental and second harmonic frequencies. A practical implementation of quasi-phase-matching is through the process of periodic polling whereby a ferroelectric material such as lithium niobate, for example, can effectively have its dipoles reversed periodically with patterned electrodes. QPM soliton propagation is an intense area of modern research and has the advantage that much larger nonlinear optical couplings can be achieved via the χ_2 nonlinearity.

Optical Breakdown in Intense Laser fields

Optical breakdown due to critical self-focusing of continuous wave laser beams or long pulses has been observed since the 1960s. The breakdown phenomenon itself is very complex and can involve nonlinear coupling to thermal, acoustic, vibrational, rotational, and electronic degrees of freedom. Thermally induced lensing, leading to critical self-focusing, is dominant for long microsecond-duration laser pulses. Nanosecond-duration laser pulses couple strongly to hypersonic acoustic waves and critical self-focusing is due to the physical mechanism of electrostriction. Picosecond-duration laser pulses typically generate electron/ion plasmas through the process of avalanche photoionization, whereas femtosecond-duration laser pulses breakdown materials predominantly via the mechanism of multiphoton ionization. The latter process is essentially instantaneous and the nonlinear ionization process is proportional to $|A|^{2N}$, where the minimum energy required to excite the bound electron to the ionization continuum is $E = N\hbar\omega$.

Figure 5. Calculated white-light supercontinuum for a high-power femtosecond laser pulse propagating in air.

Stimulated scattering processes usually accompany optical breakdown processes making it extremely difficult to unravel the relevant physics for longer duration laser pulses. Plasma, generated via avalanche ionization, acts as a shield, preventing the laser pulse from propagating further in the material. Shock waves generated in the nonlinear focal region can cause mechanical rupture for longer duration pulses.

Extreme Nonlinear Optics

The development of high-power femtosecond laser sources has led to some novel nonlinear interactions that exploit the optical Kerr effect. Single cycle pulses have been generated and very recent experimental evidence has been provided for the generation of attosecond pulses. These optical pulses are of such short duration that they interact with the atom or molecule on a timescale comparable to that taken by the electron to orbit the nucleus! The advantage of these laser sources is that many of the detrimental physical effects accompanying longer duration pulses are not operative in the femtosecond regime. Therefore, it is possible to achieve large local field intensities while maintaining low energies in the pulse. Recently, high-power femtosecond laser pulses, focused down to scales on the order of the wavelength of light, have been used to locally change the material properties of glass and write complicated integrated optics waveguiding structures. The actual mechanism for the transformation of the glass to a state with a higher refractive index is not yet fully understood.

High-power femtosecond laser pulses can propagate over anomalously long distances in air, achieving peak field intensities on the order of 10^{13} – 10^{14} W/cm². These huge intensities break down the air via multiphoton ionization in the vicinity of the nonlinear focus. Plasma, generated within the 100 μ m diameter focal spot, can act as a defocusing lens, causing the trailing edge of the laser pulse to defocus and refocus multiple times as it propagates through the atmosphere. Accompanying the extreme self-focusing is white-light supercontinuum generation.

The relatively narrow spectral peak of the initial pulse blows out asymmetrically and encompasses wavelengths ranging from the infrared to the ultraviolet. Figure 5 shows the change in the calculated white-light supercontinuum spectrum as a function of increasing pulse energy for a 100 fs-duration laser pulse propagating in air. The experimentally measured back-reflected white-light supercontinuum from a 2.6 TW 100 fs-duration laser pulse launched vertically into the atmosphere (Rairoux et al., 2000) exhibits the same qualitative features. The initial pulse spectrum is localized around the narrow peak at 800 nm. The mechanism, by which this high-power pulse sustains itself as a waveguide, is through a combination of recurring transverse modulational instabilities that create multiple intense chaotic self-focusing light strings and accompanying plasma filament generation that acts to limit the strong focusing effect (Mlejnek et al., 1999).

Another important application of high-power femtosecond laser pulses is in the generation of highly transient X-ray pulsed sources through higher harmonic cascades accompanying extreme pulse focusing. Hundreds of harmonics have been observed experimentally (Bartels et al., 2000), and novel algorithms are being developed to reshape the initial pulse so as to be able to efficiently extract a particular higher harmonic. When the pulse peak intensities exceed around 10^{17} W/cm², one enters the nonlinear regime where relativistic effects become important.

The extreme conditions encountered during critical focusing of high-power femtosecond-duration laser pulses have recently spurred theorists to question whether envelope equation models such as the NLS equation, even with higher order corrections included, can adequately describe pulse propagation under such extremes. As NLS describes quasi-monochromatic laser pulses, it is implicitly assumed in its derivation that the generated spectral bandwidth satisfies the inequality, which is the underlying optical carrier wave frequency. Experimental measurements of white-light generation in condensed media show that the spectral extent of the generated supercontinuum can exceed the initial pulse spectral bandwidth by a factor of 5 or more. The picture above for air shows that the supercontinuum extends well beyond the optical carrier frequency. Pulse propagation models that explicitly include the optical carrier wave and consequently allow for optical carrier shocks are currently under active development.

Nonlinear Optics in Photonic Bragg Structures

Periodic modulation of a material refractive index or gain offers a novel means of beating the intrinsic dispersion of available nonlinear optical materials. This idea goes back to the early days of nonlinear optics where 1-dimensional periodic index modulation allowed one

to manage or engineer the dispersion of a particular material. This is the photonic analog of the lattice periodicity leading to so-called Bloch states describing electron confinement in a semiconductor material. Just as the optical properties of semiconductor materials can be engineered by modifying the underlying lattice structure through the introduction of quantum wells or dots, so too can the optical confinement of photons be controlled by introducing a refractive index or gain periodicity in a transparent glass. Distributed feedback semiconductor lasers, based on this distributed feedback principle, are the workhorses of modern fiber-based telecommunications systems. 1-d Bragg or gap solitons have been experimentally generated in periodically modulated Kerr glass waveguides—these localized pulses have the property that they can be dramatically slowed down or even be nonpropagating within the nonlinear periodic structure.

2-d and 3-d photonic Bragg and crystal fiber structures have the special property that photonic bandgaps can be introduced in a structure consisting of a periodic lattice of holes or vertical columns. In principle, such structures can guide light around right angle bends in direct contrast to waveguide splitters, trap light in defects, and provide so-called omni-reflecting properties, that is, guide light at all angles and wavelengths. These properties are in marked contrast to conventional index-guided optical waveguides and, when combined with optical nonlinearity, offer many new potential technological applications (Mingaleev & Kivshar, 2002).

Electromagnetically Induced Transparency

Electromagnetically induced transparency (EIT) is a quantum interference effect that acts to reduce the usual absorption of light experienced when its frequency is tuned to the resonance frequency of the sample through which the light is propagating. The transparency is created by a second light (electromagnetic) source tuned to another resonance of the sample. Suppressing absorption through EIT leads to several other effects, including the focusing of one laser beam by another and the production of inversionless laser sources.

NONLINEAR PLASMA WAVES

In studying nonlinear plasma waves, one should recognize that there are several analytical methods, including single particle, fluid, and kinetic. Using the proper model is important, as different models can result in different nonlinear phenomena (Davidson, 1972; Horton & Ichikawa, 1996).

Because plasmas are composed of charged particles and are often immersed in external electric and magnetic fields, it is critical to determine when the self-consistent fields (fields produced by the charged particles directly) must be considered in the presence of externally applied fields. Typically, the self-consistent electric fields need to be considered, but we can often neglect self-consistent magnetic fields, because the forces produced by the self-consistent magnetic fields are usually much lower than those produced by external magnetic fields.

Transverse Plasma Waves

As an example of the single-particle approach, consider transverse electromagnetic (TEM) waves in a plasma. We begin with Maxwell's equations combining them to

produce the wave equation below:

$$\nabla \times \nabla \times \mathbf{E} = -\mu\sigma \frac{\partial \mathbf{E}}{\partial t} - \mu\epsilon \frac{\partial^2 \mathbf{E}}{\partial t^2}, \quad (1)$$

Where σ , ϵ , and μ are the conductivity, electric permittivity, and magnetic permeability of the plasma, respectively. We shall assume that all of the plasma effects can be collected in the permittivity and that the conductivity is part of the permittivity, so we can set $\sigma=0$ in Equation (1). If we now assume cartesian coordinates and that we have a transverse electromagnetic wave propagating in the z -direction with the propagation behaving like

$$\exp(\mathbf{k} \cdot \mathbf{r} - \omega t), \quad (2)$$

then we may substitute this notation into Equation (1) and represent Equation (1) as the matrix shown below:

$$\begin{pmatrix} -k_z^2 + \omega^2 \mu \epsilon & 0 & 0 \\ 0 & -k_z^2 + \omega^2 \mu \epsilon & 0 \\ 0 & 0 & -k_z^2 + \omega^2 \mu \epsilon \end{pmatrix} \times \begin{pmatrix} E_{0x} \\ E_{0y} \\ E_{0z} \end{pmatrix} = 0. \quad (3)$$

There are three possible eigenmodes (two of which are identical) for this equation. The first two are propagating disturbances, while the third mode is a time-invariant nonpropagating mode. In a plasma, this mode represents the electrostatic oscillations generated when the electrons are displaced with respect to the ions and allowed to move under the influence of the self-consistent (charge separation) electrostatic field. Vibrations of gelatin also exhibit this same property. If we assume that E_{0z} is zero, then the remaining two modes look just as they would in an ordinary dielectric. However, the permittivity of a plasma based on single-particle motions with stationary ions and no external d.c. magnetic field is expressed as

$$\epsilon = \epsilon_0 \left(1 - \frac{\omega_p^2}{\omega(\omega + i\nu_m)} \right), \quad (4)$$

where ν_m is the electron momentum transfer collision frequency and ω_p is the electron plasma frequency defined as

$$\omega_p^2 = \frac{ne^2}{m\epsilon_0}. \quad (5)$$

In Equation (5), n is the electron density, e is the charge of an electron, m is its mass, and ϵ_0 is the permittivity of free space. Since Equation (4) now has both real and imaginary parts, an effective conductivity of the plasma can now be obtained. Figure 1 shows a plot of the real part of ω vs. wave number k for two conditions: zero collision frequency and nonzero collision frequency. Because the relationship between k and ω is not a constant as frequency changes, we

see that a TEM wave in a plasma exhibits dispersion. Examination of the real part of the propagation vector also shows that the wave amplitude will decrease as long as the collision frequency is not zero.

Nonlinear Ion-acoustic Waves

In this example, we consider the representation of a plasma as a fluid. Under these conditions, it is possible to excite longitudinal acoustic-type oscillations. We assume that the plasma mass is concentrated in its ions but that any electric fields that are generated by charge separation appear because of the higher mobility of the electrons. In this representation, we may write the equation of motion of a fluid element as follows (Chen, 1984):

$$Mn \left[\frac{\partial \mathbf{v}_i}{\partial t} + (\mathbf{v}_i \cdot \nabla) \mathbf{v}_i \right] = en\mathbf{E} - \nabla p, \quad (6)$$

where $\mathbf{v}_i$ refers to the ion species fluid velocity, p is the pressure, M is the ion mass, and n is the plasma density. Neglecting the electron mass (for simplicity), linearizing, and assuming propagating waves as previously, $\mathbf{E}$ is the negative gradient of a scalar potential ϕ . Using the equation of state gives

$$Mn(i\omega + \nu_m)v = -en_0ik\phi - \gamma_i k T_i k n_1, \quad (7)$$

where n_0 is the steady-state density and n_1 is the perturbed density. Assuming that

$$e\phi/kT_e = n_1/n_0, \quad (8)$$

where T_e is the electron temperature, we obtain

$$(\omega + i\nu_m)v = kV_s \frac{n_1}{n_0}. \quad (9)$$

In Equation (9) V_s is the sound speed $(kT_e/M)^{1/2}$. Applying a similar analysis to the continuity equation and substituting Equation (9) we obtain

$$\begin{aligned} -i\omega n_1 + ikn_0 v &= -i\omega n_1 + ik \frac{n_0}{(\omega + i\nu_m)} [kV_s^2 \frac{n_1}{n_0}] \\ &= 0 \end{aligned} \quad (10)$$

or

$$(\omega^2 + i\nu_m\omega - k^2V_s^2) = 0. \quad (11)$$

Longitudinal Plasma Oscillations (Langmuir Waves)

Now consider the kinetic representation of a plasma, in the case where the electric field is parallel to the direction of propagation. Assuming propagation in the z -direction, an electric field in the z -direction can be developed from an electrostatic potential of the form

$$\phi = \phi_0 \exp[i(kz - \omega t)]. \quad (12)$$

Figure 1. The real part of ω versus wave number k for increasing values of collision frequency ν_m .

If there are only electrostatic forces, the velocity distribution f of the electrons is governed by the Vlasov equation:

$$\frac{\partial f}{\partial t} + \mathbf{v} \cdot \nabla f + \frac{e}{m} \mathbf{E} \cdot \frac{\partial f}{\partial \mathbf{v}} = 0. \quad (13)$$

Writing a perturbation for f as $f = f_0 + f_1$ in which f_0 is only a function of velocity and f_1 can be a function of both position and velocity, we may write the perturbed part of the Vlasov equation as

$$\frac{\partial f_1}{\partial t} + \mathbf{v} \cdot \nabla f_1 + \frac{e}{m} \mathbf{E} \cdot \frac{\partial f_0}{\partial \mathbf{v}} = 0. \quad (14)$$

Writing Poisson's equation with this ordering results in

$$\nabla \cdot \mathbf{E} = \frac{n_0 e}{\epsilon_0} \int f_1 d\mathbf{v}. \quad (15)$$

Solving Equations (14) and (15) simultaneously yields the dispersion relation for these longitudinal plasma oscillations, often called Langmuir waves, as

$$1 = \frac{n_0 \epsilon_0 e^2}{m} \frac{k}{k^2} \cdot \int \frac{\partial f_0 / \partial \mathbf{v}}{(\mathbf{k} \cdot \mathbf{v} - \omega)} d\mathbf{v}. \quad (16)$$

Note that the form of f_0 affects the dispersion relation. Also, the denominator in the integral of Equation (16) can have a singularity at which nonlinear effects can occur. It has been shown, for example, that the velocity distribution can draw energy from the wave or vice versa depending upon its slope. As a result, solitary waves can appear, expressing a balance between the driving and dissipative conditions.

In addition, Zakharov (1972) showed that Langmuir waves can evolve nonlinearly so that the electric field that results from the charge separation can become very large in a very small region. Under these "collapse" conditions, the field does not become infinitely large, but is limited by wave-particle interactions and often bursts of high-energy electrons are observed.

Plasmons

A plasmon is the resulting electrostatic oscillation described above when the velocity distribution can be neglected. For example, if it is assumed the ions in a plasma are stationary and the electrons are each uniformly displaced from their equilibrium position, then a Coulomb restoring force will be produced by the excess and deficiency of electrons at each end of the plasma, causing the electrons to oscillate about the ions. The frequency of oscillation is the electron plasma frequency:

$$\omega_p = \left(\frac{n e^2}{m \epsilon_0} \right)^{1/2}. \quad (17)$$

If the ion motion is considered, an ion plasma frequency also appears in the calculations. Plasmons, especially in solid state materials, can interact nonlinearly with electromagnetic fields and other radiation.

Plasma Turbulence

Turbulence appears when modeling for the three approaches (single particle, kinetic, and fluid) does not satisfactorily describe the experimental observations. For example, in hot plasmas, such as those appearing

in stars and fusion reactors, fluctuations in the plasma produce enhanced effects on mass, momentum and heat transport that must be studied in the context of turbulence.

If we could follow the motion of each and every particle in a plasma and its interactions with other particles and external electric and magnetic fields, we would be able to understand plasma turbulence. As that is not possible, alternative approaches must be undertaken.

Turbulence is said to appear in a plasma when the oscillations and fluctuations exhibit a continuous spectrum of frequencies. As a result of this state of turbulence, interactions between species in the plasma and the fluctuations can occur. For example, electrons, in addition to interacting with charged particles, can also interact with electric fields that are generated by the fluctuations. In addition, turbulent motion in a plasma has a very interesting effect: it can generate strong magnetic fields, producing a dynamo. This has been proposed as the mechanism for the generation of earth's magnetic field.

Numerical simulation has been shown to be a very powerful tool. In this case, the simulation involves a number of assumptions in order to make the problem solvable. The key method for these simulations involves following the trajectory of many simulation particles, as they interact with each other, that represent the plasma under various assumptions which can be applied to particular problems. By use of large supercomputers, it is possible to simulate astronomical and fusion plasma phenomena and examine the structure of the turbulence. A color figure in the color plate section shows a cross section of the results of such a simulation for a toroidal magnetic confinement system called a Tokamak. Calculations of this scale of detail could not be done without numerical simulations.

Whistlers and Helical Waves

Whistler waves have been detected in the ionosphere and have been attributed to the change of phase and group velocities of a right circularly polarized plasma wave that travels along the earth's magnetic field. The dispersion relation for this mode is

$$k^2 = \omega^2 \mu_0 \epsilon_0 \left[1 - \frac{\omega_{pi}^2 + \omega_{pe}^2}{(\omega + \omega_{ci})(\omega - \omega_{ce})} \right]. \quad (18)$$

In the ionosphere, the frequency of the waves is lower than the electron cyclotron frequency. Thus, the phase velocity (ω/k) , which can be found from Equation (18) increases with frequency, and the group velocity also increases. When a lightning discharge takes place, an electromagnetic disturbance that has a large continuous spectrum of components is produced. The disturbance will travel to the ionosphere and then propagate along the Earth's magnetic field lines. However, the

lower frequency components of the disturbance will take longer to arrive at a receiving station than the higher frequency components; thus, the received signal appears as a signal that decreases in frequency with time.

In examining the behavior of the electric field vector for a right circularly polarized wave, we note that as the wave propagates along an external magnetic field line, the direction of the electric field rotates around the direction of propagation which is, in this case, the direction of the magnetic field. As a result, this or any other mode can be represented as a helical wave in which the rotation of the end of the electric field vector traces out a helical path as it propagates.

MHD Kink Waves in Toroidally Confined Fusion Plasmas

The sine-Gordon equation has been shown to describe the trajectory of the "slinky" mode in a reversed-field-pinch magnetic fusion experiment (Ebraheem et al., 2002). A reversed-field-pinch experiment produces a magnetic field in a torus in which the portion of the field that is in the toroidal direction (the long way around) is reversed in its outer regions from that closer to the minor axis of the torus. Experimentally, it has been seen that during the operation of the system, magnetohydrodynamic (MHD) fluctuations in the center of the plasma can coalesce into a rotating "hot spot" that travels around the torus. Under some circumstances, the rotating mode may lock to other disturbances or to particular locations on the vacuum chamber torus.

As the mode may be envisaged as a helical solitary wave, it lends itself to being represented by the sine-Gordon equation. The mechanical transmission line analogy (Scott, 1971) can be applied here, if it is assumed that the MHD mode is a solenoid that wraps helically around the torus. The gravitational restoring torque can be represented as the gradient of the magnetic energy of the magnetic moment of the mode in the externally generated magnetic fields of the torus due to toroidal effects (the magnetic field on the inside of the torus is stronger than at the outside of the torus). The spring torque due to the adjacent pendula can be modeled by recognizing that the current flowing around the turns of the solenoid tends to make the solenoid align itself along its axis, so any disturbance from the alignment results in an equivalent spring torque.

Parametric Decay Instability

Consider two oscillators that have different resonant frequencies ω_1 and ω_2 that are nonlinearly coupled to each other through a third oscillator of resonant frequency ω_0 . We assume that the oscillators are normal

modes of various types in the plasma such as described above. If each of these waves is considered from the point of view of quantum theory, interactions are governed by conservation of energy:

$$\hbar\omega = \hbar\omega_1 + \hbar\omega_2 \quad (19)$$

and conservation of momentum

$$k_0 = k_1 + k_2, \quad (20)$$

where k represents the wave number for each mode. The zero subscript refers to the “pump” mode and the other two modes are referred to as the “daughter” modes (Rost et al., 2002).

Assume that two of the oscillators obey the following equation of motion where each is driven by a time-dependent force that is proportional to the amplitude of a pump oscillator E_0 :

$$\frac{d^2x_1}{dt^2} + \omega_1^2x_1 = c_1x_2E_0, \quad (21)$$

$$\frac{d^2x_2}{dt^2} + \omega_2^2x_2 = c_1x_1E_0, \quad (22)$$

where c_1 and c_2 are nonlinear coupling constants. If E_0 is made to vary in time at frequency ω_0 , it can be seen that both modes can be driven by a frequency not equal to their natural frequency and, in addition, each oscillator's motion is coupled to the other oscillator's equation of motion.

See Damped-driven anharmonic oscillator

NONLINEAR SCHRÖDINGER EQUATIONS

The basic nonlinear Schrödinger (NLS) equations are

$$iu_t \pm \frac{1}{2}u_{xx} + |u|^2u = 0, \quad (1)$$

where $u(t, x)$ is a complex function, the real variables t and x are frequently (but not always, see below) time and space coordinates, and the subscripts indicate partial derivatives. The upper and lower signs in front of the second term in Equation (1) correspond, respectively, to self-focusing and self-defocusing NLS equations, to be denoted below as NLS(+) and NLS(−).

NLS equations attracted much attention after Zakharov & Shabat (1972) demonstrated that Equations (1) are integrable by means of the inverse scattering transform (IST) (Zakharov et al., 1984). Under this formulation, Equation (1) is viewed as a compatibility condition for a system of two auxiliary linear equations for a two-component function $\psi^{(1,2)}(x, t)$. The first of these equations is

$$\begin{pmatrix} -i\partial_x & u^*(x) \\ -u(x) & i\partial_x \end{pmatrix} \begin{pmatrix} \psi^{(1)} \\ \psi^{(2)} \end{pmatrix} = \lambda \begin{pmatrix} \psi^{(1)} \\ \psi^{(2)} \end{pmatrix}, \quad (2)$$

where λ is a spectral parameter and the asterisk stands for the complex conjugation. The first step in the application of IST is to solve the direct scattering problem for Equations (2) (also called Zakharov–Shabat (ZS) equations) with a given initial configuration $u_0(x)$ at $t = 0$, that is, to map $u_0(x)$ into a set of scattering data. In the general case, the set contains continuous and discrete components, which correspond, respectively, to real and complex λ . The temporal evolution of scattering data, generated by the temporal evolution of $u(x, t)$ under Equation (1), turns out to be trivial, so that, once the scattering data is known at $t = 0$, it is also known for any $t > 0$. Finally, at given t , one must recover the field $u(t, x)$ from the known scattering data, that is, to solve the inverse scattering problem, which is based on the Gel'fand–Levitan–Marchenko integral equation.

The simplest solution of NLS(+) represents a soliton (exponentially localized pulse)

$$u_{\text{sol}} = \eta \operatorname{sech} [\eta (x - ct - x_0)] \times \exp (icx - i\omega_{\text{sol}}t + i\phi_0), \quad (3)$$

where $\omega_{\text{sol}} = (c^2 - \eta^2)/2$, $\operatorname{sech} z \equiv 2(e^z + e^{-z})^{-1}$, η and c are arbitrary amplitude and velocity of the soliton, and x_0 and ϕ_0 are the coordinate of the soliton's center and its phase at $t = 0$.

Note that frequencies of the zero-velocity ($c = 0$) solitons are negative ($\omega_{\text{sol}} = -\eta^2/2 < 0$), while the frequencies of radiation modes, that is, solutions to the linearized version of NLS(+), $u_{\text{rad}} = u_0 \exp(ikx - i\omega_{\text{rad}}t)$, are positive ($\omega_{\text{rad}} = k^2/2 > 0$, where k and u_0 are arbitrary wave number and amplitude). Thus, solitons exist

in a part of the frequency space where radiation modes are absent, exemplifying a general principle: solitons cannot share frequencies with radiation, as they would otherwise be losing energy through the emission of linear waves.

In terms of the IST, the soliton corresponds to a case when the continuous component of the scattering data is absent, while the discrete component consists of a single eigenvalue $\lambda = (-c + i\eta)/2$. All the solutions corresponding to an arbitrary set of complex eigenvalues can be found in an explicit form, describing collisions between solitons unless their velocities coincide. The solitons reappear after the collision with the same amplitudes and velocities, that they had prior to the collision, the only change being shifts of the constants x_0 and ϕ_0 . If velocities coincide, the solution describes a bound state of solitons, which is dynamically unstable because its binding energy is zero. Thus, the simple soliton given by Equation (3) is the single stable solution to NLS(+) with a permanent wave shape.

Besides the solitons, Equations (1) have spatially uniform solutions in the form of continuous waves (CWs), $u_{\text{CW}}(t) = \eta \exp(\pm i\eta^2 t)$, with an arbitrary real amplitude η . An important issue is stability of the CW solutions against small perturbations. To investigate the stability, one can represent a solution as $u(t, x) = a(x, t) \exp(i\phi(t, x))$, where $a(t, x)$ and $\phi(t, x)$ are real amplitude and phase. Rewriting Equation (1) as a system of real equations for a and ϕ leads to a perturbed CW with $a(t, x) = \eta + a_1(t, x)$, and $\phi(t, x) = \pm \eta^2 t + \phi_1(t, x)$, with infinitesimal perturbations a_1 and ϕ_1 . Linearizing the equations with respect to a_1 and ϕ_1 yields a solution in the form

$$\begin{aligned} a_1(x, t) &= a_1^{(0)} \exp(\sigma t) \cos(px), \quad \phi_1(x, t) \\ &= \phi_1^{(0)} \exp(\sigma t) \cos(px), \end{aligned} \quad (4)$$

where $a_1^{(0)}$ and $\phi_1^{(0)}$ are infinitesimal amplitudes of the perturbation, p is its arbitrary wave number ($-\infty < p < +\infty$), and σ is an instability growth rate. The linearized equations imply the following relation between σ and p :

$$\sigma^2(p) = \pm p^2 (\eta^2 \mp p^2/4). \quad (5)$$

The necessary and sufficient condition for the stability of CW against small perturbations is $\text{Re } \sigma(p) \leq 0$, which must hold for all p . As is seen from Equation (5), all the CW solutions to NLS(-) are stable, but in NLS(+) they all are unstable for p^2 in the range $0 < p^2 < 4\eta^2$. It follows from Equation (4) that growing perturbations break the uniformity of the CW, initiating spatial modulation. This is called modulational instability and also Benjamin–Feir instability, after the authors who discovered it in the context of water waves.

Although NLS(-) does not support solitary-wave solutions, it has a stable solution in the form of a dark

soliton (DS), which is a region of low amplitude moving on top of a CW. The DS solution is

$$\begin{aligned} u_{\text{DS}} &= \eta \exp(i\eta^2 t) \\ &\times \{(\cos \theta) \tanh[\eta(\cos \theta)(x - ct)] + i \sin \theta\}, \end{aligned} \quad (6)$$

where η is the amplitude of the CW background, and θ , which takes values between 0 and $\pi/2$, determines the minimum value of the field at the center of DS and its velocity (Kivshar & Luther-Davies, 1998). The solution of Equation (3) is sometimes called a bright soliton to stress its difference from the DS.

A fundamental property of NLS equations which is not related to the integrability and is therefore more generic, being shared by a broad class of equations, is a possibility to represent the equations in the Lagrangian and Hamiltonian forms. The general Lagrangian representation is $\delta S/\delta u^*(t, x) = 0$, where $S\{u(t, x), u^*(t, x)\}$ is an *action functional*, which must be real, and $\delta/\delta u^*$ stands for the variational (Fréchet) derivative of the functional (u and u^* are treated as independent functional arguments). The action functional that generates Equation (1) is

$$S = \int dt \int_{-\infty}^{+\infty} dx [i(u^* u_t - u u_t^*) \mp |u_x|^2 + |u|^4]. \quad (7)$$

The Hamiltonian representation of the NLS equations is

$$i \frac{\partial u}{\partial t} = \frac{\delta H\{u, u^*\}}{\delta u^*}, \quad (8)$$

where the Hamiltonian (H) is $\int dx (\pm |u_x|^2/2 - |u|^4/2)$. The representation in the form of Equation (8) is very general, applying to a large class of equations for complex fields.

For real H , it follows from Equation (8) that the Hamiltonian is conserved. From the perspective of the Noether theorem, conservation of H is a consequence of the fact that Equation (1) is invariant with respect to an arbitrary time shift, $t \rightarrow t + t_0$. The invariances with respect to an arbitrary phase shift, $u(t, x) \rightarrow u(t, x) \exp(i\phi_0)$, and to an arbitrary coordinate shift, $x \rightarrow x + x_0$, generate the conservation of the number N (alias “number of quanta”) and momentum P , which are given by universal expressions, irrespective of the particular form of the equation:

$$\begin{aligned} N &= \int_{-\infty}^{+\infty} dx |u(x)|^2, \\ P &= \frac{1}{2} i \int_{-\infty}^{+\infty} dx (u u_x^* - u^* u_x). \end{aligned} \quad (9)$$

If the equation is integrable by means of IST, it possesses, in addition to the dynamical invariants N ,

P , and H , an infinite series of higher-order conserved quantities (Zakharov et al., 1984).

Despite the exact integrability of Equation (1) by means of IST, the solution provided by this technique may be too cumbersome; therefore, a more tractable approximate method for the construction of solutions is often desirable. To this end, a variational approximation (VA), whose applicability relies solely on the Lagrangian representation of the equation(s), has been developed for solitons of NLS(+) and for several other equations, including those described below. This method approximates the full PDE by a low-order system of ODEs, which are derived from the same action functional (Malomed, 2002).

NLS Models for Wave Envelopes in Weakly Nonlinear Dispersive Media

Equations (1) also appear as universal equations governing the evolution of slowly varying packets of quasi-monochromatic waves in weakly nonlinear media featuring dispersion (dependence of the wave's group velocity c_{gr} on its frequency ω).

To illustrate this point, one can take the sine-Gordon (SG) equation, $\psi_{tt} - \psi_{xx} + \sin \psi = 0$, for real $\psi(t, x)$. Assuming a small-amplitude wave with a slowly varying complex envelope function $u(t, x)$ carried by a high-frequency wave $\exp(-it)$, the solution is $\psi(t, x) = u(t, x) \exp(-it) + u^*(t, x) \exp(it)$, where the slow variation implies that $|u_t|^2 \ll |u|^2$. Substituting into SG, expanding $\sin \psi$ up to the cubic term, dropping the higher-order small terms u_{tt} and u_{tt}^* , and separately collecting terms in front of two independent rapidly varying functions $\exp(\pm it)$ yields two equations: NLS(+) for $u(t, x)$, and its complex conjugate for $u^*(t, x)$.

Thus, NLS equations can be derived as equations governing the evolution of weakly nonlinear wave packets in various media. An important example is light propagation in nonlinear optical fibers and planar waveguides. In the former case, NLS takes the normalized form $iu_z \pm (1/2)u_{\tau\tau} + |u|^2 u = 0$, where $u(\tau, z)$ is the local amplitude of the electromagnetic wave, which is a function of the propagation distance z and $\tau \equiv t - z/c_{gr}$ (c_{gr} is the group velocity of light in the fiber). In the context of Equation (1), z plays the role of the evolutionary variable, and τ plays the role of the coordinate. The cubic term in the equation accounts for the Kerr effect (a nonlinear correction to the refractive index), while the upper and lower signs in front of $u_{\tau\tau}$ correspond to the anomalous and normal chromatic dispersion in the fiber, $dc_{gr}/d\omega > 0$ and $dc_{gr}/d\omega < 0$, respectively (ω is the frequency of the electromagnetic wave). Only anomalous dispersion gives rise to bright optical solitons (also called temporal solitons) as they are localized in τ (Agrawal, 1995). Temporal

solitons are important in fiber-optic telecommunications.

In planar waveguides, spatial bright solitons are possible in the form of self-confined light beams. In this case, the propagation coordinate z again replaces t in Equation (1), while the transverse coordinate x appears the same way as in Equation (1), the term u_{xx} accounting for diffraction of light in the waveguide. The corresponding NLS equation is always self-focusing.

Other significant applications in which NLS equations arise are small-amplitude gravity waves on the surface of deep inviscid water and Langmuir waves in hot plasmas (collective oscillations of electrons relative to ions). However, these media are not really one-dimensional, which makes the corresponding NLS solitons unstable against transverse perturbations.

In plasma, NLS(+) approximates a more fundamental model—the Zakharov system

$$\begin{aligned} iu_t + \frac{1}{2}u_{xx} + nu &= 0, \\ n_{tt} - n_{xx} &= -(|u|^2)_{xx}, \end{aligned} \quad (10)$$

where $n(t, x)$ is a perturbation of the ion density, and $u(t, x)$ is the local amplitude of the Langmuir waves. Although Equations (10) are not integrable, they generate stable solitons and reduce to NLS(+) in the adiabatic limit, when the term n_{tt} may be neglected.

Zakharov's system is a universal model describing weakly nonlinear waves in dispersive media, where a dominating process is the interaction between high- and low-frequency waves (e.g., the Langmuir and ion-acoustic waves, respectively, in plasmas). Another example is the interaction of high-frequency (near infra-red) molecular vibrations and low-frequency (far infra-red) longitudinal deformations in a model of long biological molecules, which gives rise to the Davydov soliton.

Generalized Forms of the Nonlinear Schrödinger Equations

The NLS equation can be viewed as a paradigmatic representative of a large class of nonlinear PDEs, some of which are also integrable. Examples are the derivative NLS equation, $iu_t + u_{xx} + i(|u|^{2u})_x = 0$, whose integrability was discovered by Kaup and Newell (this equation applies to Alfvén waves in magnetized plasmas), the Hirota equation, $iu_t + u_{xx} + i(u_{xxx} + 6|u|^2 u_x)$, and the Sasa–Satsuma equation, $iu_t + u_{xx} + i[u_{xxx} + 6|u|^2 u_x + 3(|u|^2)_x u] = 0$.

In applications to fiber optics, an important generalization considers two polarizations of light (or two different wavelengths in one fiber), leading to a

system of coupled NLS equations

$$\begin{aligned} iu_z \pm \frac{1}{2}v_{\tau\tau} + (|u|^2 + \beta|v|^2)u &= 0, \\ iv_z \pm \frac{1}{2}v_{\tau\tau} + (|v|^2 + \beta|u|^2)v &= 0. \end{aligned} \quad (11)$$

In the case of linear polarizations, $\beta = \frac{2}{3}$, and in the case of circular polarizations or different wavelengths, $\beta = 2$ (Agrawal, 1995). As demonstrated by Manakov, Equations (11) are integrable if $\beta = 1$ (Manakov, 1974).

Generalized NLS equations are not integrable in other cases of interest, including the multidimensional NLS equations

$$iu_t \pm \frac{1}{2}\nabla^2 u + |u|^2 u = 0, \quad (12)$$

where ∇^2 is the two- or three-dimensional (2-d or 3-d) Laplacian. Equation (12) describes light propagation in bulk media, and Langmuir waves in plasmas. Both the 2-d and 3-d solitons are unstable because NLS(+) gives rise to collapse, that is, formation of a singularity in finite time (Bergé, 1998) (nevertheless, the 2-d soliton, also called the Townes soliton, plays an important role, as it determines the critical power necessary for the collapse in the 2-d case).

The 2-d NLS(−) gives rise to vortex solutions, with important implications in nonlinear optics, which take the form

$$u = \eta \exp(i\eta^2 t + iS\chi) U(\sqrt{2}\eta r) \quad (13)$$

with arbitrary η and $U(\rho = \infty) = 1$. Here, χ is the angular coordinate in the 2-d space, and $S \geq 1$ is an integer vorticity. Only the vortex with $S = 1$ is stable, being a 2-d counterpart of the DS solution (6) with $\theta = 0$.

Multidimensional bright solitons (also called light bullets in 3-d optical models) may be stable if the cubic term $|u|^2 u$ in NLS(+) is replaced by a saturable one, $|u|^2 (1 + |u|^2/u_0^2)^{-1} (u_0^2 = \text{const})$, or by a combination of self-focusing cubic and self-defocusing quintic terms, $(|u|^2 - |u|^4)u$. In the latter case, bright 2-d solitons with the embedded vorticity $S \geq 1$ and 3-d solitons with the vorticity $S = 1$ may also be stable.

Similar to Equation (12) is the Gross–Pitaevskii (GP) equation for the single-atom wave function $\psi(t, \mathbf{r})$, on which the mean-field description of Bose–Einstein condensates is based (Dalfovo et al., 1999):

$$i\hbar \frac{\partial \psi}{\partial t} = -\frac{\hbar^2}{2m} \nabla^2 \psi + U(\mathbf{r})\psi + g|\psi|^2 \psi. \quad (14)$$

Here $\hbar$ is Planck's constant, m is the atom mass, $U(\mathbf{r})$ is a trapping potential, and g is proportional to the scattering length of collisions between atoms, which may be both positive and negative.

The simplest approach to GP is to seek a stationary solution, $\psi(t, \mathbf{r}) = \exp(-i\mu t/\hbar) \Psi(\mathbf{r})$ (μ is called the chemical potential), and apply the Thomas–Fermi approximation to $\Psi(\mathbf{r})$, which amounts to dropping the Laplacian in Equation (14). This yields

$|\Psi(\mathbf{r})|^2 = g^{-1}[\mu - U(\mathbf{r})]$ if it is positive, or $\Psi = 0$ otherwise.

Nonlinear optics motivate examples of coupled NLS equations that are different from Equations (11). Propagation of light in an optical fiber carrying a Bragg grating (a lattice of defects with the period equal to half the wavelength of light, which gives rise to mutual resonant conversion of right- and left-traveling waves) is described by equations for the amplitudes $u(t, x)$ and $v(t, x)$ of the counterpropagating waves,

$$\begin{aligned} iu_t + iu_x + (|u|^2 + 2|v|^2)u + v &= 0, \\ iv_t - iv_x + (|v|^2 + 2|u|^2)v + u &= 0 \end{aligned} \quad (15)$$

with the linear coupling accounting for the resonant Bragg scattering. The spectrum of the linearized version of Equations (15) is $\omega^2 = k^2 + 1$, hence it has a radiation-free gap, $-1 < \omega < +1$, where solitons may be expected. A family of gap solitons is generated by Equations (15) that can be found exactly although Equations (15) are not integrable and not all members of this family are stable (de Sterke & Sipe, 1994; Malomed, 2002).

Another NLS system describes a basic process in nonlinear optics—second harmonic generation (SHG). If the nonlinearity is quadratic, the system is

$$\begin{aligned} iu_z + \frac{1}{2}u_{xx} + u^*v &= 0, \\ 2iv_z + \frac{1}{2}v_{xx} + \frac{1}{2}v^2 + qv &= 0, \end{aligned} \quad (16)$$

where $u(z, x)$ and $v(z, x)$ are amplitudes of the fundamental-frequency and second harmonic waves, and real q is a wave number mismatch between the harmonics. Equations (16) are written for the realistic case of spatial fields in a planar waveguide. They give rise to a family of solitons in the form $u = \exp(ikz)U(x)$, $v = \exp(2ikz)V(x)$, with exponentially localized $U(x)$ and $V(x)$. Except for the case $k = q/3$, the solitons are not available in an analytical form, but most of them are stable (Etrich et al., 2000). Multidimensional generalizations of Equations (16) give rise to stable solitons too, as collapse does not take place in the SHG model.

Ginzburg–Landau (GL) equations, which are formally similar to NLS equations, provide general models of nonlinear dissipative media. The simplest GL equation is Equation (1) with all the coefficients made complex. In general, however, dynamics generated by GL equations is altogether different from that governed by NLS equations (Aranson & Kramer, 2002).

NONLINEAR SIGNAL PROCESSING

The field of nonlinear signal processing is an active area of research stimulated by a combination of new applications, advances in technology, and fundamental advances in mathematical theory. The breadth of applications has extended far beyond the original emphasis on communications to disciplines such as brain science, financial analysis, image and voice recognition, cryptography, virtual reality, digital photography and printing technology, and neural computing. Significant accelerations in computing speeds and the increasingly widespread availability of computer clusters have made more complex algorithms computationally feasible and motivated the investigation of a much larger range of algorithms. Included in these new algorithms are techniques extracted, for example, from chaos theory, partial differential equations, computational geometry, support vector machines, numerical analysis on manifolds, and optimization theory. Fundamental advances in nonlinear signal processing have centered around an increased mathematical understanding of the notion of information content and representation.

Nonlinear signal processing began with the realization that all components of a signal are not equal. For example, nonlinear filters have been used for compressing signals associated with telephone voice communications where the fidelity required depends on the frequency of the signal. In general, it is possible to retain fewer bits of high frequency data than lower frequency

data and still maintain voice clarity. Additionally, median and min/max filters and histogram equalization represent traditional tools in nonlinear signal (and image) processing. In mathematical terms, the motivation for nonlinear signal processing techniques arises from the geometric structure, or organization, of the data. In some idealized sense, we can view data as either being flat, as possessing some degree of curvature, or having a fractal nature. The nature of this structure in the data dictates the best tool to be used for its analysis. For example, *signal dimension* is an important feature of a signal. Based on the geometry of the signal, one may employ, for example, basis dimension, topological dimension, or Hausdorff dimension. There are now a number of methods that have been proposed to detect nonlinear features in data including poly-spectral analysis, surrogate analysis, and more; see Barnett et al. (1997) for detailed comparisons.

As a consequence of the inherently complicated geometry, modeling nonlinear signals is significantly more challenging than their linear counterparts. For example, an n -dimensional linear signal may be written $f(x(t)) = Ax(t)$ where the model consists of the $m \times n$ matrix of parameters. If there are more points than unknowns to construct the model, then the approach of least squares may be used for solving overdetermined systems. This theory, including the effect of perturbations on the data, is well understood. For nonlinear signals with n -dimensional domains, one encounters the well-known “curse of dimensionality” that suggests that the amount of data required to construct such nonlinear mappings is exponentially dependent on the dimension of the domain. However, the recognition that this problem is overcome by judiciously placing basis functions in the domain of the data has led to a large literature in the theory and applications of modeling nonlinear signals in high dimension. Radial basis functions (RBFs) are a popular choice and have the form

$$f(x) = w_0 + \sum_{k=1}^N w_k \phi(\|x - c_k\|),$$

where the vectors c_k are the special sites of the basis functions, x the domain value and the w_i the model parameters. The basis functions may be local, for example, $\phi(r) = \exp(-r^2)$ or global, for example, $\phi(r) = r^3$. Artificial neural networks (ANNs) have also been proposed for such nonlinear approximation tasks. These networks provide a flexible, or adaptive, tool to *learn* a function. Generally, a special type of ANN is employed, that is, a feed-forward sigmoidal network. Mathematically, this may be expressed as

$$y = \sum_i w_i^{(2)} \sigma \left(\sum_j w_{ij}^{(1)} x_j - \theta_i \right),$$

where σ is a monotonic nonlinear squashing function and $\{w_i^{(2)}, w_{ij}^{(1)}, \theta_i\}$ the model parameters. There exist universal approximation theorems that state under which conditions both the RBF and ANN approximations can produce models to essentially arbitrary accuracy. Of course, practical issues such as computation expense and parsimony of the model must be considered in the implementation of such methods. Further details on these issues may be found in Haykin (1994) and Kirby (2001).

Dynamical systems theory has provided a new paradigm for the analysis of nonlinear signals. Fuelled by observation that complex or chaotic signals can arise from simple nonlinear deterministic systems, a suite of new tools has been developed for their empirical detection, characterization, and design. Briefly, a discrete dynamical system may be viewed as the iteration of a mapping, that is

$$x^{(n+1)} = f(x^{(n)}). \quad (17)$$

Often the trajectory $\{x^{(0)}, x^{(1)}, x^{(2)}, \dots\}$ traces out a complicated path. Here $x^{(n)}$ is viewed as a function of n . However, a *delay embedding* that plots a point as a function of the previous one or more points may produce a picture that reveals the structure of the simple underlying deterministic system. For example, the well-known logistic map has the form

$$x^{(n+1)} = \alpha(1 - x^{(n)})x^{(n)}.$$

It possesses a complicated, apparently random trajectory with broad Fourier spectrum for $\alpha > 4$. However, clearly the locus of points $(x^{(n)}, x^{(n+1)})$ is a parabola. Thus, one is motivated to look for structure in a sequence of observations of a signal by constructing the delay embeddings $(x^{(n)}, x^{(n-1)})$ (one delay) or $(x^{(n)}, x^{(n-1)}, x^{(n-2)})$ (two delays) and so on. In practice, it is useful to explore delays of multiples of an integer, that is, $N, 2N, 3N, \dots$

This heuristic approach gains some credibility with the support of the Takens embedding theorem; see for example, Abarbanel (1996) and references therein. To get a flavor of the power of this theorem, consider a multidimensional discrete dynamical system, that is, the point $\mathbf{x}^{(n)}$ being iterated is a d -tuple. Takens's theorem basically says that if we are able to observe any one component of this system, for example $\{x_1^{(n)}\}$ then the delay embedding of this variable produces a geometrical structure that is in some sense equivalent to the original system. Furthermore, if only a function h of the first component is observed $h(x_1^{(n)})$, then we can still replicate the structure of the original system with the delay embedding approach. The number of delays required to achieve this embedding is prescribed by Takens, for example if the dynamical system resides on

an m -dimensional manifold, then the number of delays need only be $2m + 1$ (Abarbanel, 1996).

The dynamical system described by Equation (17) or the delay mapping

$$x^{(n+1)} = f(x^{(n)}, x^{(n-1)}, \dots),$$

where f is unknown but observed data are available may also be modeled using the RBF or ANN approaches. Note that the domain of this mapping of delay coordinates may be of high enough dimension to preclude the use of other standard methods. A first look at this procedure in the context of nonlinear signal modeling is described in Lapedes & Farber (1987).

Yet another promising direction of the dynamical systems approach is fractal image compression. Here a picture may be stored as an *iterated function system*, that is two or more systems of the form of Equation (17) where f is now an affine transformation. An image can be produced by iterating this system and only a small number of parameters need be stored. See Barnsley & Hurd (1993) for many interesting examples as well as mathematical details.

The richness of the nonlinear signal processing field is in part due to technology. Optical signal processing is based on the application of the characteristics of light to process and transmit information. For example, in optical image processing, holograms are used to store data while lenses are used to compute two-dimensional Fourier transforms and may also perform edge detection and filtering tasks (Poon & Banerjee, 2001). Most recently, the field of fiber optics has arisen from the observation that light emanating from a laser and passing through a tiny pure glass pipe can transmit more information than electrical signals transmitted along a wire. The ability to send and amplify multiple signals simultaneously along an optic fiber has give rise to data transmission rates of 10 Gbps with higher rates in view. This technique is referred to as dense wavelength division multiplexing (DWDM) (Ramaswami & Sivarajan, 2001). New efforts to model and exploit such technologies suggest that the field of nonlinear signal processing is at the dawn of a new era. For example, the emerging area of photonics addresses how light can be used to represent and process signals and the new discipline of biophotonics concerns how light may be used to discover the mechanisms by which the basic building blocks of living matter function. Signal processing problems such as these may prove to have significant impact on the human condition including the battle against diseases such as cancer.

NONLINEAR SUPERPOSITION

See *N-soliton formulas*

NONLINEAR TOYS

Toys are ubiquitous and some are unique to particular cultures. Many action toys are intriguing because they perform in unexpected ways as a result of underlying nonlinear principles, yielding both amusement and surprises for the unwary. Here we give several examples of toys and devices that operate on linear and nonlinear physical principles.

Frog on a Swing

Several toys are based on the mechanism of *parametric excitation*. Although primarily a linear mechanism, an increase in amplitude in parametric excitation leads to the nonlinear range of amplitude-dependent phenomena. One can demonstrate parametric excitation by taking a string with a weight attached to its end and make it into a pendulum by hanging it over the forefinger (see Figure 1(a)). Now, force the weight into a small amplitude oscillation, and then move the weight up and down with the same phase as the oscillation by pulling on the string periodically. The result is an increase in the amplitude of the oscillation of the pendulum. The phase of the oscillation will vary slowly as the amplitude increases and the inherently nonlinear nature of the pendulum becomes important. The basic linearized equation for parametric excitation of the nonlinear pendulum is the Mathieu equation

$$\frac{d^2\theta}{dt^2} + (\omega_0^2 - \alpha \sin 2\omega_0 t) \theta = 0$$

Figure 1. Parametric excitation demonstrated by (a) a pendulum over a finger and (b) a frog on a swing.

where θ is the angle of the pendulum from the vertical, ω_0 is the fundamental small amplitude frequency, and α is the amplitude of the periodically changing pendulum length.

This principle of parametric excitation is active in the toy called the “frog on a swing” (see Figure 1(b)). The frog in this toy is made of rubber and sits on a swing (pendulum). It can be inflated periodically with air using a tube and bulb. This causes the frog to stand up and sit down repeatedly and, hence, moves the center of mass of the frog up and down, as illustrated in Figure 1(b). With proper timing in inflating the bulb at the correct phase during each swing, the amplitude of the swing with the oscillating frog on it gradually increases. The same principle applies to the playground swing where children can increase the amplitude of their swing by “pumping” the swing in a standing position (Wirkus et al., 1998).

Handstand Pendulum

A related, but completely different, phenomenon occurs in the “handstand pendulum.” The normal pendulum hangs stably downwards from its fulcrum as a result of gravity. However, applying a high-frequency forced oscillation to the fulcrum can cause the pendulum to be inverted, so that it now “hangs” stably pointing upwards

Figure 2. The handstand pendulum.

(Figure 2). Again the governing linearized equation is the Mathieu equation, but with the signs changed:

$$\frac{d^2\theta}{dt^2} + \left(-\frac{g}{\ell} + 2\alpha \sin 2\omega t\right)\theta = 0$$

where g is the acceleration due to gravity and ℓ is the length of the pendulum arm.

Shishi-odoshi

In some Japanese gardens, there is a device that was designed originally to scare deer and other animals away from rice fields. Now, its purpose is either to scare away the deer that may intrude into a garden to eat the plants or to serve as an aesthetic fixture in the garden for its novelty and silence breaking “clack.” This device, while not strictly a toy, is based on nonlinear principles and is called a *shishi-odoshi* (deer-scarer) or *shika-oi*. The *shishi-odoshi* is made from a thick bamboo culm with a length of three internal cells, that is, four nodes (the raised rings at regular intervals along the bamboo). At one end, the last node has been cut off and the end shaped to receive water (see Figure 3). From this open end, the internal membrane of the first node also has been removed so there is a cylindrical cup that is two cells long. A pivot rod is inserted into the bamboo between the two inner nodes so that when the tube is empty, the closed end of the bamboo rests on a stone. However, the position of the pivot is chosen so that as a steady stream of water flows into the open end of the tube, the center of mass of the bamboo and water shifts across the pivot and the open end of the tube will dip down, thus pouring out the water. The empty tube now returns quickly to its stable position on the stone with a loud “clack,” which is the noise that is supposed to scare the deer.

The oscillatory motion of the bamboo tube caused by the steady flow of water is called a *relaxation oscillation* and can be regarded as an example of a self-induced oscillation. There are many toys that use this principle to change their orientation periodically, namely, water filling up a reservoir, and then the water being discharged as a result of the change of orientation of the toy.

Figure 3. Bamboo deer alarm.

Figure 4. A tippe top in its stable resting position and stable rotating position.

Figure 5. The pecking woodpecker with a detail of the spring in (a).

Tippe Top

A fascinating toy is the tippe top, which does not act like a conventional top. The tippe top consists of a little more than a hemisphere with a short cylindrical stem (see Figure 4(a)). It has a low center of gravity, so when placed on a surface, it will simply sit like an ordinary top on its hemispheric side. However, if the stem is held between a finger and the thumb and given a spin on the hemispheric end, then unlike a conventional top, the tippe top will readily turn over and continue to spin on the stem (see Figure 4(b)). As it turns over, the behavior of the tippe top is unusual in two respects: the center of gravity is raised and the spinning direction with respect to fixed body coordinates is reversed. When the top is spun, the low center of gravity is centrifugally moved away from the vertical spin axis. Before and after the top turns over, the angular momentum of the top about the vertical axis is the dominant momentum component. During the inversion process, the center of gravity is raised and the increase in potential energy reduces the rotational kinetic energy. The torque needed to execute

Figure 6. Two other toys that use self-induced oscillations.

this inversion comes from the sliding frictional forces between the top's hemispherical surface and the surface on which it is rotating. The mechanics of this top are described by nonlinear equations of motion that are solvable only in special cases (Cohen, 1977; Or, 1994; Gray & Nickel, 2001).

Pecking Woodpecker

A cute toy providing entertainment for young children is the pecking woodpecker going down a pole. To make this toy, coil a soft wire loosely around a smooth pole to make a soft spring. Now leave several turns of the coil on the pole and the remaining coils extended outwards from the pole (see Figure 5a). The weight of the protruding part of the spring will tilt the spring coiled around the pole so that the static friction is sufficient to keep it fixed on the pole. If one pushes the extended coil downwards and releases it, the extended coil vibrates up and down and the spring around the pole descends in a staccato fashion. The reason for the stuttering movement down the pole is that the coil around the pole oscillates periodically between being stopped by static friction and essentially free falling down the pole when the coil is aligned with the pole. Now attach a small wooden bird to the end of the extended wire, and the bird will peck the pole with its beak as it descends the pole (see Figure 5b).

There are many toys that move by the principle of self-induced oscillation (see Figure 6). The basic equations for such oscillations are those of Duffing and van der Pol.

NONLINEAR TRANSPARENCY

See **Nonlinear optics**

NONLINEARITY, DEFINITION OF

If a system's response to an applied force is directly proportional to the magnitude of that force, the system is said to be linear, otherwise the system is nonlinear. Nonlinear dynamics is concerned with systems whose time evolution equations are nonlinear.

As an example of a linear system, consider the one-dimensional motion of a point mass connected to a spring of force constant k , subject to a force

$$F_x(x) = -kx$$

in the x -direction. If k is changed, then the frequency and amplitude of resulting oscillations will change, but the qualitative nature of the behavior (simple harmonic oscillation in this example) remains the same. In fact, by appropriately rescaling the length and time axes, we can make the behavior for any value of k look just like that for some other value of k . For nonlinear systems, on the other hand, a small change in a parameter can lead to sudden and dramatic changes in both the qualitative and quantitative behavior of the system.

Although almost all natural systems are nonlinear, many of them respond in an approximately linear way provided that the amplitude of the force is

small enough. This is one of the reasons why traditional linear approximations are so popular in science. Another reason is that the analytical solution of nonlinear equations is often difficult. With the development and availability of computers, however, numerical solutions of nonlinear equations became relatively easy in the 1970s. This focused attention on important nonlinear phenomena such as deterministic chaos, although the idea of dynamic chaos was first glimpsed by Henri Poincaré (Poincare, 1908). Nonlinearity and the phenomena that result from it have a strong bearing on the concept of determinism.

Given a set of variables (position, velocity, acceleration, pressure, the number of species in a chemical reaction, etc.) or a function of two or more independent variables that describe the state of a system, the subsequent time evolution can be represented as causal relationship between its present state and its next state in the future. The existence of causality in such relationships is suggested by all our experience of experimenting with Nature, and it corresponds to the deterministic perception of the evolution of dynamical systems.

Consider, for example, the oscillatory motion of a damped pendulum in the phase space of two variables, the angle θ and the velocity v

$$\dot{\theta} = v,$$

$$\dot{v} = -\gamma v - \omega_0^2 \sin(\theta),$$

where γ and ω_0^2 are parameters that describe damping rate and frequency of small oscillations. These time evolution equations can be written in operator form as

$$L\theta = \frac{d^2\theta}{dt^2} + \gamma \frac{d\theta}{dt} + \omega_0^2 \sin(\theta) = 0. \quad (1)$$

Formally, the dynamics is linear if the causal relation between the present state and the next state is linear, otherwise it is nonlinear. In the above example, the dynamics will be linear if we replace the term $\beta \sin(\theta)$ with its linear approximation $\beta\theta$ near the asymptotically stable equilibrium state $\theta=0$, $v=0$. The corresponding linear operator in this case satisfies the property that

$$L^{(\text{lin})}(ax + by) = aL^{(\text{lin})}x + bL^{(\text{lin})}y,$$

where a and b are real numbers and x and y are differentiable functions. The property of linear superposition plays a fundamental role in the analysis of linear equations of motion, and represents one of the basic principles of quantum mechanics (Landau & Lifshitz, 1977). If the property of linear superposition does not hold the dynamics is nonlinear.

On physical grounds, dynamical systems are in general nonlinear. Indeed, if we consider small deviations of a pendulum from its state of unstable

equilibrium $\theta = \pi$, $v = 0$ and replace the nonlinear term by its linear approximation $\omega_0^2 \sin(\pi + \delta\theta) \approx -\omega_0^2 \delta\theta$, we find unbounded growth of $\delta\theta$ in time. However, the experimentally observed motion of the pendulum is bounded; that is, the character of the motion changes when the deviation from the point of unstable equilibrium is large. Thus, nonlinearity corresponds to the situation that arises when the properties of the system depend directly on its state. The latter property, on one hand, makes a nonlinear system difficult to analyze but, on the other hand, gives rise to a rich diversity of nontrivial phenomena. We now consider briefly two consequences of nonlinearity.

First, the spectrum of oscillations of a nonlinear system is a complex function of its state (see, e.g., Sagdeev et al., 1988). For example, for weakly nonlinear oscillations of the pendulum near the state of stable equilibrium, we find (Hayashi, 1964), neglecting damping, that the frequency ω varies with the amplitude of the oscillations A as

$$\omega \approx \omega_0(1 - 3/64A^3).$$

The dependence of the frequency of oscillations on the state of the system is a key feature of many phenomena, including harmonic generation, synchronization, and the formation of solitons (See **Harmonic generation; Solitons; Synchronization**).

Second, a prominent effect of nonlinearity is the onset of deterministic chaos. Linear dynamical systems can have only three types of invariant sets: fixed points, cycles, and quasi-periodic orbits. The occurrence of a chaotic orbit is possible only in nonlinear systems and can be viewed in simple terms as arising from the interplay between the instability and nonlinearity. The instability is responsible for the exponential divergence of two nearby trajectories, whereas the nonlinearity bounds trajectories within a finite volume of the phase space of the system. The combination of these two mechanisms gives rise to a high sensitivity of the system to the initial conditions (See **Butterfly effect**). Consequently, the onset of deterministic chaos is restricted to nonlinear systems and involves repeated stretching and folding. The simplest example of a nonlinear system that demonstrates chaotic behavior through this process is a Bernoulli shift: $x_{n+1} = 2x_n \pmod{1}$. An important consequence of chaos is that the predictability of even simple nonlinear systems is limited, so that ergodic theory has to be used to describe their statistical properties.

From these two brief examples it is already clear that in nonlinear science, the whole is more than the sum of its parts.

The complexity and diversity of the possible types of behavior in nonlinear systems have been widely explored in physics and chemistry, including analyses of solitons, nonlinear localization, pattern formation,

and formulation of the general principles of self-organization.

The formalism of nonlinear systems provides a framework for understanding and modeling of the hierarchy of complexity in the life sciences. However, there are many difficulties to be encountered on the way. In particular, Hermann Haken (in Tschacher & Dauwalder, 1999) notes:

“While in physics or chemistry it is not too difficult to define the microscopic and macroscopic levels, with respect to the brain we must ask what adequate intermediate levels we have to choose between microscopic and macroscopic.”

An example of a practical approach to the solution of this problem arose during the investigation of neurons (See **Neurons**). Although the ionic current through the axon membrane is successfully described by the Hodgkin–Huxley equations, heart fibrillation is more conveniently modeled by the continuous FitzHugh–Nagumo equation, which is a simplified version of Hodgkin–Huxley system. On passing to models of neural networks, the hierarchy of connections between neurons structured in time turn out to be of prime importance, but this raises new questions for nonlinear science related to the appearance of closed causal loops. Continuing this hierarchy, one may expect that the application to cognitive science of complexity theory derived from nonlinear analysis will have a major impact on our understanding of reasoning, thinking, behavior, and psychology generally (Tschacher & Dauwalder, 1999).

NONTWIST MAPS

Two-dimensional area-preserving mappings have become a standard tool for analyzing two-degrees-of-freedom autonomous and one-and-one-half dimensional time-periodic Hamiltonian systems (Lichtenberg & Lieberman, 1990). Prominent among such mappings are the radial twist maps

$$T : \begin{cases} p' = p - DU(q), \\ q' = q + f(p'), \end{cases} \tag{1}$$

where q and p are conjugate variables, $U(q)$ and $f(p)$ are smooth functions, and D is a derivative operator. For example, with $U = -K \cos q$ and $f(p) = p$, we recover the standard map, which has become a paradigm for chaotic Hamiltonian dynamics.

Usually $f(p)$ is monotonic, in which case the twist $\tau = df/dp$ does not change sign. The twist condition, $\tau \neq 0$, is crucial for the validity of such linchpins of stability theory as the Moser twist theorem and the Kolmogorov–Arnol’d–Moser (KAM) theorem Arnol’d. Nevertheless, more and more instances have been found where the twist condition is violated, for example, plasma wave heating, zonal flows in planetary magnetospheres, beam dynamics in particle accelerators, and relativistic charged particle motion. The proliferation of such nontwist maps has challenged theorists to find alternatives to standard tools of nonlinear dynamics.

The Standard Nontwist Map

Many of the essential characteristics of nontwist maps are captured in the standard nontwist map (SNTM) (Howard and Hohs, 1984)

$$\begin{aligned} p' &= p - K \sin q, \\ q' &= q + p' - \alpha p'^2, \end{aligned} \tag{2}$$

where K and α are positive constants. Thus, the twist vanishes along the line $p = 1/2\alpha$. An equivalent version is discussed in del Castillo-Negrete et al. (1997). Generalizations employing higher order polynomial forms for $f(p)$ are discussed in Howard & Humphreys

Figure 2. Reconnection scenario for standard nontwist map.

(1995). Fixed points are located at $q \in (0, \pi)$ and

$$p_n^\pm = \frac{1 \pm \sqrt{1 - 8\pi n \alpha}}{2\alpha}. \tag{3}$$

For positive n both roots are positive real for $0 \leq 8\pi n \alpha \leq 1$, merging in a saddle-node bifurcation when $\alpha^* = (8\pi n)^{-1}$ at $p^* = 4\pi n$. Figure 1 shows the SNTM for $K = 1.5$ and two nearby values of α . Notice that, in contrast to the standard map, stable and unstable fixed points are staggered in phase rather than vertically aligned. This leads to a new kind of global bifurcation, called *reconnection* of KAM curves (by analogy with magnetic reconnection), which occurs when

$$\begin{aligned} K(\alpha) &\approx \frac{1}{2} \int_{p^-(\alpha)}^{p^+(\alpha)} [f(\xi; \alpha) - 2\pi n] d\xi \\ &= \frac{(1 - 8\pi n \alpha)^{3/2}}{12\alpha^2}. \end{aligned} \tag{4}$$

The entire reconnection scenario is depicted schematically in Figure 2. We see that for a given configuration of X- and O-points, there are two topologically distinct arrangements of separatrices. Thus, in going from Figure 2(a) to (c), the upper separatrix is diverted downward, looping around the lower elliptic point. In between (b) the two separatrices merge, a

Figure 3. Vortex pair formation in the standard nontwist map for $K = 4.0$ and (a) $\alpha = 0.0260$, (b) $\alpha = 0.02634$.

process called *braiding*. Finally, Figure 2(d) shows the characteristic cusps resulting from the merging of X- and O-points via a saddle-node bifurcation. Naturally, the structure of the full mapping (Figure 1) is much more complicated than this approximate depiction. Of particular interest is the band of meandering curves seen in Figure 1(b), which constitute a new kind of barrier to chaotic transport. More complex sequences occur for more complex $f(p)$.

Higher-order fixed points also undergo reconnection. For example, the period-two islands near $p = 6\pi$ exhibit a second kind of reconnection, *vortex pair* formation, as shown in Figure 3. Here the elliptic and hyperbolic fixed points are vertically aligned, in contrast to the staggered pairs of period-one islands seen in Figure 1. An exhaustive classification of possible reconnection scenarios has not yet been accomplished.

As in the case of monotone twist maps, the location of higher order fixed points is facilitated by writing the map as a composition of involutions, $T = I_2 I_1$ ($I_1^2 = I_2^2 = I$). Fixed points of T then lie on the intersections of the invariant curves of I_1 and I_2 . For the general twist map (1) we have

$$I_1 : \begin{cases} p' = p - DU, \\ q' = -q, \end{cases} \tag{5}$$

$$I_2 : \begin{cases} p' = p, \\ q' = -q + f(p). \end{cases} \quad (6)$$

Mappings with this decomposition are called *reversible*; that is, there exists a symmetry S such that $T^{-1} = STS$. Explicitly, $S = I_2$, so that $T^{-1} = I_1 I_2$.

Normal Forms

In investigating the structure of a 2-dimensional symplectic map near a stable fixed point (Howard & MacKay, 1987), it is useful to employ Birkhoff normal forms. Thus, the mapping T written in action-angle variables J and θ takes the simple form (Meyer & Hall, 1992)

$$\begin{aligned} J' &= J \\ \theta' &= \theta + 2\pi\Omega(J). \end{aligned} \quad (7)$$

Here the rotation number is given by

$$\Omega(J) = \omega + \tau_0 J + \frac{1}{2} \tau_1 J^2 + \dots \quad (8)$$

and the twist by

$$\tau = \frac{\partial \Omega}{\partial J} = \tau_0 + \tau_1 J + \dots, \quad (9)$$

where τ_0 and τ_1 are the zero and first-order twists. In this way it has been shown (Moeckel, 1990; Dullin et al., 1999) that a twistless torus is generated for any area-preserving map near a tripling bifurcation, where $\omega = \frac{1}{3}$.

Transition to Global Chaos

In many physical applications of nontwist maps, the transition to global chaos is of paramount importance, as space-spanning KAM curves (invariant rotational circles) act as barriers to particle or energy transport (Meiss, 1992; Lichtenberg & Lieberman, 1990). The breakdown of such barriers is usually studied via some kind of renormalization theory, such as that devised by Greene et al. (1981) for area-preserving maps satisfying the twist condition. Greene's method is based on the conjecture that the last KAM curve to break up with increasing perturbation strength has rotation number equal to the inverse of the golden mean, that is, $\omega_c = 1/\gamma = (\sqrt{5} - 1)/2$. Using the involution decomposition to locate a sequence of periodic orbits whose rotation number $\omega \rightarrow 1/\gamma$, he found the critical value $K_c = 0.9716\dots$. Recently, del Castillo-Negrete et al. (1997) have succeeded in modifying Greene's semi-analytic method to obtain an accurate estimate for the breakup of the $\omega = 1/\gamma$ invariant circle for the SNTM. This calculation is complicated by the facts that (i) periodic orbits come in pairs for nontwist maps and may even fail to exist for certain parameters (K , α for the SNTM), and (ii) the sequence of periodic orbits actually has six convergent subsequences. Preliminary work has also been carried out on developing a suitable renormalization treatment for nontwist maps.

Extension to Higher Dimension

It is of interest to ask whether nontwist maps exist in higher dimension and what sort of reconnection processes might occur. This may be done in a natural way by letting $p, q \in \mathbb{R}^n$. The Birkhoff normal form then depends on the frequency map, $\Omega(J) = DS(J)$, where S is a scalar function of J . The twist, in turn, becomes the $n \times n$ Jacobian matrix $\tau(J) = D\Omega(J) = D^2S(J)$, and the frequency map suffers a singularity whenever $\det \tau$ passes through zero. Dullin & Meiss (2003) have determined the behavior of four-dimensional symplectic maps near such a singularity. Again, a twistless torus appears near a 1 : 3 resonance but with interesting topological complications. In four dimensions the frequency map can have a fold or a cusp singularity—in higher dimensions other catastrophes can occur.

NORMAL FORMS THEORY

Many nonlinear systems can be modeled by ordinary, differential, or difference equations, and a central problem of dynamical systems theory is to obtain information on the long-time behavior of typical solutions. Because it is not possible, in general, to solve these equations explicitly, we identify particular solutions (such as equilibrium solutions or periodic

solutions) and try to infer global information from the behavior of nearby solutions.

As an example, consider an equilibrium state such as the downward position of a pendulum. Looking at small perturbations of this position to identify nearby periodic orbits (corresponding to small oscillations of the pendulum) shows that the downward pendulum is indeed stable. Analysis of the inverted pendulum reveals that it is unstable, in the sense that nearby solutions do not stay close to the equilibrium position.

Mathematically, an equilibrium is a fixed point of a dynamical system, and the stability analysis is carried out by linearizing the system, that is, by replacing (close to the fixed point) the nonlinear equations by linear equations for the perturbations. The resulting linear system can be solved exactly, and the analysis of these solutions may give information about the behavior of the solutions of the nonlinear system around the fixed point. This method is extremely powerful when it works, and is the basis of much dynamical system analysis. In some cases, however, the behavior of the linear system may be entirely different from that of the nonlinear system, and no information can be obtained from the linear analysis. This implies that there is crucial information contained in the nonlinear terms.

Normal forms theory is a general method designed to extract this information. The basic idea is to compute a local change of variables to transform a nonlinear system into a simpler nonlinear system that contains only the essential nonlinear terms—those that cannot be neglected without drastically changing the nature of the system. Hopefully, the new system is either linear or can be solved explicitly.

Consider the normal form analysis of the zero fixed point of systems of two differential equations of the form

$$\begin{aligned}\dot{x}_1 &= a_{11}x_1 + a_{12}x_2 + f_1(x_1, x_2), \\ \dot{x}_2 &= a_{21}x_1 + a_{22}x_2 + f_2(x_1, x_2),\end{aligned}\quad (1)$$

where the dots denote time derivatives and f_1 and f_2 are nonlinear analytic functions whose Taylor expansion about the origin contains no linear term. Linear analysis of the fixed point at the origin is carried out by neglecting the nonlinear terms and considering the linear system $\dot{x}_1 = a_{11}x_1 + a_{12}x_2$, $\dot{x}_2 = a_{21}x_1 + a_{22}x_2$. The dynamics of this system is governed by the eigenvalues λ_1, λ_2 of the matrix (a_{ij}) , which is assumed to be diagonalizable. If the eigenvalues have nonvanishing real parts, then the dynamics of the original nonlinear system is qualitatively equivalent to the dynamics of the linear system and the fixed point is stable if both real parts are negative and unstable as soon as one of the real parts is negative. However, if the eigenvalues are imaginary, the behavior of the nonlinear system cannot be inferred from analysis of the linear system, and the information on the stability of the origin is contained in the nonlinear terms. For example, the origin of the

system $\dot{x}_1 = x_2$, $\dot{x}_2 = -x_1 + \alpha x_1^2 x_2$ is either stable or unstable depending on the sign of α .

The first step in the normal form analysis of system (1) is to introduce a linear change of variables so it reads

$$\begin{aligned}\dot{y}_1 &= \lambda_1 y_1 + g_1(y_1, y_2), \\ \dot{y}_2 &= \lambda_2 y_2 + g_2(y_1, y_2).\end{aligned}\quad (2)$$

Second, look for a near-identity change of variables in the form of power series $y_1 = z_1 + P_1(z_1, z_2)$, $y_2 = z_2 + P_2(z_1, z_2)$ that simplifies system (2). To this end, expand g_1, g_2 in power series and choose the coefficients of the series P_1, P_2 so that in the z_1, z_2 variables, the system $\dot{z}_1 = \lambda_1 z_1 + h_1(z_1, z_2)$, $\dot{z}_2 = \lambda_2 z_2 + h_2(z_1, z_2)$ becomes simpler than the original system. Optimally, $h_1 = h_2 = 0$, which would provide an exact linearization of the original system. In general, however, some nonlinear terms remain after transformations.

It turns out that the ability to exactly linearize the original system is intimately connected to the eigenvalues λ_1, λ_2 . If either $(n_1 - 1)\lambda_1 + n_2\lambda_2 = 0$ or $n_1\lambda_1 + (n_2 - 1)\lambda_2 = 0$ for some positive integers n_1, n_2 , the eigenvalues are said to be resonant (or in resonance), and in general one of the functions (h_1 or h_2) contains resonant terms of the form $z_1^{n_1} z_2^{n_2}$. In the absence of resonance, therefore, no nonlinear terms remain and exact linearization is achieved.

If the eigenvalues are purely imaginary, z_2 is the complex conjugate of $z_1 = z$, and there are infinitely many resonance conditions. The stability of the fixed point is then decided by the first non-vanishing coefficient of h_1 . As an example, consider again the system $\dot{x}_1 = x_2$, $\dot{x}_2 = -x_1 + \alpha x_1^2 x_2$. After the linear change of variable $x_1 = y_1 + y_2$, $x_2 = i(y_1 - y_2)$, we have

$$\begin{aligned}\dot{y}_1 &= iy_1 + (\alpha/2)(y_1^2 y_2 - y_1 y_2^2 - y_2^3 + y_1^3), \\ \dot{y}_2 &= -iy_2 - (\alpha/2)(y_1^3 - y_1^2 y_2 + y_1 y_2^2 + y_2^3).\end{aligned}\quad (3)$$

The normal form transformation to third order reads:

$$\begin{aligned}y_1 &= z_1 + (i\alpha/8)(2z_1^3 + 2z_1 z_2^2 - z_2^3) + \text{h.o.t.}, \\ y_2 &= z_2 + (i\alpha/8)(z_1^3 - 2z_1^2 z_2 - 2z_2^3) + \text{h.o.t.},\end{aligned}\quad (4)$$

where h.o.t. denotes higher-order terms of degree 5 and higher. Finally, the normal form becomes

$$\begin{aligned}\dot{z}_1 &= iz_1 + (\alpha/2)z_1 z_2^2 + \text{h.o.t.}, \quad z_2 = z_1^*, \\ \dot{z}_2 &= -iz_2 + (\alpha/2)z_2 z_1^2 + \text{h.o.t.}\end{aligned}\quad (5)$$

From Equations (5), $\dot{\rho} = (\alpha/2)\rho^3 + \text{h.o.t.}$ where $\rho^2 = z_1 z_2$, which implies that the origin of the initial system is stable if $\alpha \leq 0$ and unstable otherwise.

If all coefficients of the normal forms vanish identically, then the fixed point is surrounded by an open set of periodic orbits (a nonlinear center). The downward position of the frictionless pendulum is an example of a center. Note, however, that the convergence of the power series P_1, P_2 is not guaranteed, in general, and further conditions on the eigenvalues and the transformation must be satisfied.

For a general N -dimensional system of differential equations, we can compute the linear eigenvalues $\lambda_1, \dots, \lambda_N$. If the real part of one of these eigenvalues vanishes, there is no guarantee that the dynamics of the linear system is equivalent to the dynamics of the nonlinear system close to the fixed point. Again, one can find explicit near-identity power series change of variables that simplify the original system. If $n_1\lambda_1 + n_2\lambda_2 + \dots + n_N\lambda_N = \lambda_i$ for any i between 1 and N and for positive integers $n_1, n_2, \dots, n_N$, then the eigenvalues are in resonance, and the i th new equation will contain some resonant nonlinear terms. This resonance relation is one of the most fundamental relations in nonlinear dynamics. It determines whether linear modes (determined by the eigenvectors of eigenvalues λ) are coupled by the nonlinear terms. It is the same resonance relation that appears in different guises in the analysis of forced linear systems and in the resonance between frequencies in Hamiltonian and celestial mechanics. Essentially, in the absence of resonances, the system evolves following the linear modes and no interaction is possible. When resonances occur, the linear modes interact through the nonlinear terms and create complex dynamics.

Normal forms theory provide a systematic way to include the effect of the nonlinear terms. At the practical level, the method as presented tends to be rather tedious because the number of monomials that have to be taken into account grows rapidly with the dimension of the system and the degree of the normalizing transformation. There are several equivalent alternatives to the computation of normal forms, including the method of "amplitude equation" for ordinary and differential equations and the Birkhoff–Gustavson transformation for Hamiltonian systems. Nevertheless, at the conceptual level, normal forms theory is a central tool to understand the rich dynamics of nonlinear systems and this general framework can be used to study and give a rigorous foundation to many other problems beside stability.

A particularly important use of normal form theory is the theory of bifurcations. In order to identify generic bifurcations, one considers the parameters of the system $\mu_1, \dots, \mu_M$ as additional variables satisfying trivial differential equations $\dot{\mu}_i = 0$, $i = 1, \dots, M$ and studies the normal forms of this extended system of dimension $N + M$, revealing the nature of the bifurcation. Other applications of normal forms include the analysis of chaotic systems in systems of differential equations, the formation of patterns for partial differential equations, exponentially small effects in the splitting of separatrices, and the Painlevé theory of integrable systems.

N-SOLITON FORMULAS

A one-soliton solution of an evolutionary nonlinear partial differential equation in one spatial dimension $u_t = F(u, u_x, u_{xx}, \dots)$ is a solitary wave (pulse) of finite energy and momentum. As an example, the Korteweg–de Vries (KdV) one-soliton is the exact solution

$$u(x, t) = \frac{-2\kappa_1^2}{\cosh^2(\kappa_1(x - \xi_1) - 4\kappa_1^3 t)}, \quad (1)$$

to the KdV equation

$$u_t = -u_{xxx} + 6uu_x. \quad (2)$$

Note that Equation (1) has the shape of a negative well, moving at a speed that is proportional to the depth.

N -soliton solutions are characterized by the fact that, for $t \rightarrow -\infty$ and $t \rightarrow +\infty$, the shape of the solution is composed by a quasi-exact superposition of N non-interacting pulses of the form (1). This means that the shape of the solution for $t \rightarrow -\infty$ is a sequence of N wells, ordered according to their depth, the deepest being the leftmost. For $t \rightarrow +\infty$, the shape is also a sequence of wells, with now the deepest being the rightmost, each of them retaining the original shape. The solution pictorially describes a family of N individual pulses traveling at their own characteristic speeds, the faster ones catching up with the slower, and, after an interaction, reemerging with their individual shapes. The overall effect of the nonlinear interaction is a phase shift between the pulses (that is, a difference in the relative distances of the dips of the wells). It can be proved that, in the collision process of N solitons, the total phase shifts are the sum of phase shifts of two-soliton processes.

The presence of N -soliton solutions, for arbitrary N , is often regarded as the hallmark for integrability of a nonlinear PDE. Three main methods have been devised for constructing and studying N -soliton solutions:

- The inverse scattering method (ISM), based on the Gel'fand–Levitan–Marchenko (GLM) equations
- Hirota's formalism
- Bäcklund transformations

Here we present formulas making explicit reference to the ISM. For direct ways of finding N -soliton solutions, we refer to the entries on Hirota's method and on the Darboux and Bäcklund transformations.

In the ISM, the existence of N -soliton solutions is associated with the following mathematical feature.

A nonlinear integrable evolution equation (say, for one dependent variable u defined on the real line), is presented as a Lax (isospectral) equation for a linear operator $L(u)$,

$$\frac{d}{dt}L(u) = [B(u), L(u)], \quad (3)$$

where the bracket indicates a commutator ($[B, L] \equiv BL - LB$). The spectrum of $L(u)$, as an operator in $L^2(R)$, is the union of the point spectrum $\lambda_1, \lambda_2, \dots$ and the continuous spectrum, consisting of the intervals $I_1 \cup I_2 \dots$. An N -soliton solution of (3) is a solution associated with an initial data $u(x, 0)$ whose spectrum contains only a finite number N of points. Such initial data are often called reflectionless potentials.

Given N -soliton initial data, the direct spectral problem for $L_0 = L(u(x, 0))$, gives (in addition to the spectrum) normalization coefficients β_i of the eigenfunctions corresponding to the eigenvalues λ_i , $i = 1, \dots, N$. The evolution equations of the parameters $\beta_i = \beta_i(t)$ are linear equations with coefficients that depend on the constants λ_i . Accordingly, an N -soliton solution describes $2N$ -dimensional families of solutions parametrized by the point spectrum of the linear operator and by the normalization coefficients β_i .

Two Soliton Solutions for Korteweg-de Vries and Sine-Gordon Equations

For the KdV equation (2) let $\lambda_1 = -\kappa_1^2$ and $\lambda_2 = -\kappa_2^2$ ($\kappa_1 > \kappa_2$) be the points in the spectrum of the Lax operator $L = -d^2/dx^2 + u$, and let ξ_i be quantities associated with the normalization coefficients $\beta_i(0)$ of the eigenvector of L . In other words, κ_i, ξ_i is the scattering data of the reflectionless potential $u(x, 0)$. A two-soliton solution for KdV is

$$u(x, t) = \frac{2\kappa_1^2 (\kappa_1 - \kappa_2) (\kappa_1 + \kappa_2) \left(\cosh^2(\phi_2) + (\kappa_2/\kappa_1)^2 \cosh^2(\phi_1) - 1 \right)}{(\kappa_2 \cosh(\phi_1) \cosh(\phi_2) - \kappa_1 \sinh(\phi_1) \sinh(\phi_2))^2},$$

where $\phi_i = \kappa_i (x - \xi_i) - 4\kappa_i^3 t$.

This is an instance of the phenomenon described above. Indeed, for $t \rightarrow -\infty$ the solution describes two pulses traveling in the positive x -direction, with the faster one (that is, the one pertaining to the data κ_1, ξ_1) being the leftmost one.

The solution describes the process whereby the fast soliton catches up to the slow one, and finally (for $t \rightarrow +\infty$), the two emerge. The shape of the individual pulses remains unchanged, the effect of the nonlinear interaction being a phase shift. The fast soliton experiences a positive phase shift of

$$\Delta\phi_1 = \frac{1}{\kappa_1} \log \left| \frac{\kappa_1 + \kappa_2}{\kappa_1 - \kappa_2} \right|,$$

while the slow soliton loses the same phase (see Figure 1).

Figure 1. Phase shifts in two soliton collision.

The two-soliton solution of the sine-Gordon (SG) equation

$$\frac{\partial^2 u}{\partial t^2} - \frac{\partial^2 u}{\partial x^2} + \sin u = 0,$$

in terms of the points λ_1, λ_2 in the spectrum of the corresponding Lax operator and the constants c_1, c_2 is given by

$$u(x, t) = \frac{\frac{c_1}{2\lambda_1} \exp\left(-\frac{x-v_1 t}{\sqrt{1-v_1^2}}\right) + \frac{c_2}{2\lambda_2} \exp\left(-\frac{x-v_2 t}{\sqrt{1-v_2^2}}\right)}{4\text{arctg} \frac{1 - \frac{c_1 c_2}{4\lambda_1 \lambda_2} \frac{(\lambda_1 - \lambda_2)^2}{(\lambda_1 + \lambda_2)^2} \exp\left(-\frac{x-v_1 t}{\sqrt{1-v_1^2}} - \frac{x-v_2 t}{\sqrt{1-v_2^2}}\right)}},$$

where $v_i = (4\lambda_i^2 - 1)/(4\lambda_i^2 + 1)$, $i = 1, 2$. The fast soliton undergoes a positive phase shift given by

$$\Delta\phi_1 = \sqrt{1 - v_2^2} \log \frac{(\lambda_1 + \lambda_2)^2}{(\lambda_1 - \lambda_2)^2},$$

while the slow soliton undergoes a negative phase shift:

$$\Delta\phi_2 = -\sqrt{1 - v_1^2} \log \frac{(\lambda_1 + \lambda_2)^2}{(\lambda_1 - \lambda_2)^2}.$$

General Formulas

General formulas for N -soliton solutions of soliton equations are usually expressed in terms of determinants. For certain well-known soliton equations, one has the following results.

(1) Korteweg-de Vries (KdV) equation:

$$u_N(x, t) = -2 \frac{d}{dx^2} \log \det(A),$$

where A is a $N \times N$ matrix with elements

$$A_{ij} = \delta_{ij} + \frac{\beta_i(t)}{\kappa_i + \kappa_j} \exp(-(\kappa_i + \kappa_j)x),$$

where $\beta_i(t) = \beta_i(0) \exp(8\kappa_i^3 t)$.

(2) Sine-Gordon (SG) equation:

$$u_N(x, t) = 2i \log \frac{\det(A_+)}{\det A_-},$$

where

$$[A_{\pm}]_{ij} = \delta_{ij} \pm \frac{c_j}{\lambda_i + \lambda_j} \exp(\gamma_j(x, t)),$$

$$\text{with } \gamma_j(x, t) = -i(\lambda_j + \frac{1}{4\lambda_j})t + i(\lambda_j - \frac{1}{4\lambda_j})x.$$

(3) Nonlinear Schrödinger (NLS) equation:

$$i \frac{\partial \psi}{\partial t} + \frac{\partial^2 \psi}{\partial x^2} - 2g|\psi|^2 \psi, \quad g = \pm 1.$$

The N -soliton solutions are given by

$$\psi(x, t) = \frac{i}{\sqrt{g}} \frac{\det M_1(x, t)}{\det M(x, t)},$$

where

$$M_{ij}(x, t) = \frac{1 + \bar{\gamma}_i(x, t)\gamma_j(x, t)}{\bar{\lambda}_i - \lambda_j}$$

and the $N+1 \times N+1$ matrix $M_1(x, t)$ is described as follows:

$$M_1 = \begin{array}{|cc|} \hline M & G \\ \hline 1 & \dots & 1 & 0 \\ \hline \end{array}$$

where G is the vector $(\gamma_1(x, t), \dots, \gamma_N(x, t))$, with $\gamma_i(x, t) = \gamma_i^{(0)} \exp(i\lambda_i x - i\lambda_i^2 t)$.

(4) Infinite Toda Lattice (ITL): The ITL equations are compactly written in the Lax form:

$$\frac{dL}{dt} = [B, L],$$

where L is the infinite matrix with b_i on the principal diagonal and a_i on the first lower and upper diagonal, and B is the antisymmetric matrix having a_i on the first lower diagonal; the coefficients $\{a_i, b_i\}$ are related to the canonical variables $\{Q_i, P_i\}$ by the transformation

$$a_i = \frac{1}{2} \exp(-(Q_{i+1} - Q_i)/2), \quad b_i = \frac{1}{2} P_i.$$

N -soliton solutions are given by the formula:

$$\exp(-(Q_i - Q_{i-1})) = \frac{\det B_i \det B_{i-2}}{(\det B_{i-1})^2},$$

$$P_i = \text{const.} + \frac{d}{dt} \log \frac{\det B_{i-1}}{\det B_i}.$$

In this formula the B_i 's are $N \times N$ matrices with elements given by

$$[B_i]_{j,k} = \delta_{j,k} + \gamma_j(t) \gamma_k(t) \frac{(\lambda_j \lambda_k)^{i+1}}{1 - \lambda_j \lambda_k},$$

$$j, k = 1, \dots, N.$$

The λ_j are the N elements of the point spectrum of L , and the γ_j are normalization constants; the time dependence of the solution is given by

$$\gamma_j(t) = \gamma_j(0) \exp(\pm \sinh(\sigma_j)t), \quad \lambda_j = \pm \exp(-\sigma_j).$$

Further Comments

The formulas above can be interpreted as nonlinear superposition formulas for soliton solutions. Indeed, N -soliton solutions are constructed via the definition of suitable matrices determined by the spectral data associated with individual solitons. More precisely, the notion of nonlinear superposition principle can be better understood in the framework of the theory of Darboux–Bäcklund transformations.

In general, N -soliton solutions can be obtained as suitable limits of periodic solutions of the same system as the period tends to infinity. Periodic finite gap solutions are obtained by means of theta functions defined over Riemann surfaces. N -soliton solutions are obtained by letting suitable homology cycles of such Riemann surfaces shrink to a (degenerate) surface (with nodes and cusps) of genus equal to zero.

NUMERICAL METHODS

Numerical methods are used for approximations of “exact” mathematical solutions, which either do not exist or are very complicated. With fast computer processors and advanced mathematical software, many problems become more attractive for numerical rather than for analytical solutions.

Computational Errors

Numerical computations are always uncertain because the results are only defined within the accuracy of a numerical error. Two main reasons account for errors in numerical approximations: finite precision in computer representation of numbers, and truncation of exact mathematical formulas in numerical algorithms.

Finite precision defines the tolerance interval, within which any further improvement in a numerical solution is impossible. For instance, the precision accuracy of MATLAB on the Windows platform is order of 10^{-16} . Therefore, it is meaningless to initialize irrational numbers (such as π or e) beyond the 16th digit after the period while carrying computations in MATLAB.

Round-off errors can be obstacles for accurate numerical approximations. Numerical differentiation algorithms are typically ill-posed since the round-off error increases with smaller step size of numerical discretization. Catastrophic cancellations can occur due to round-off errors, as in the example below when two large nearly identical numbers are subtracted:

$$f(x) = \sqrt{x+1} - \sqrt{x}.$$

If $x = 1.00000000000000 \times 10^{10}$, then $\sqrt{x+1} = 1.00000000050000 \times 10^5$, $\sqrt{x} = 1.00000000000000 \times 10^5$ and

$$f(x) = 4.999994416721165 \times 10^{-6}.$$

However, if the relative round-off error is order of 10^{-10} , the result is identical to zero. If the precision accuracy cannot be extended, a modification of the numerical procedure is required for a more accurate answer, as in the equivalent representation:

$$f(x) = \frac{1}{\sqrt{x+1} + \sqrt{x}}.$$

Within the same precision accuracy, the result is now $f(x) \approx 4.9999999999 \times 10^{-6}$.

Truncation errors occur due to chopping of an infinite series into a finite number of terms. For example, the Taylor series for analytical functions can be truncated with the Taylor polynomials, as in the example:

$$e^{x^2} = 1 + x^2 + \frac{1}{2!}x^4 + \frac{1}{3!}x^6 + E(x),$$

where $E(x)$ is the truncation error. The integral of e^{x^2} on $x \in [0, 1]$ is given in terms of a special function,

called the error function. Equivalently, this integral can be approximated with the Taylor polynomial as

$$\int_0^1 e^{x^2} dx = \left(x + \frac{1}{3}x^3 + \frac{1}{10}x^5 + \frac{1}{42}x^7 \right) \Big|_{x=0}^{x=1} + E_{tr} \\ = 1.457142857142857 + E_{tr},$$

where the truncation error is $E_{tr} \approx 5.508914448636659 \times 10^{-3}$.

Numerical algorithms are classified by the rate of convergence and by their numerical stability (i.e., will a small error decay or grow through the successive iterations). Convergence and stability of numerical algorithms are studied with analysis of the truncation error. If the truncation error depends on the step size h of the finite numerical discretization and reduces as h^n , then the numerical algorithm is said to converge to an exact solution as the n th-order algorithm. As an example, we consider a numerical computation of the integral, given by irrational number e :

$$e = \int_0^1 f(x) dx, \quad f(x) = 1 + e^x.$$

Using the discretization of the unit interval with N equal subintervals of the step size $h = 1/N$, we can use the composite trapezoidal rule to approximate the integral as

$$e = \frac{h}{2} \left(f(0) + 2 \sum_{n=1}^{N-1} f(hn) + f(1) \right) + E(h),$$

where the theoretical truncation error is $E(h) = \alpha_2 h^2$ and α_2 is constant, such that $\lim_{h \rightarrow 0} \alpha_2 \neq 0$. The composite trapezoidal rule converges to the integral as the second-order method. Indeed, computing the algorithm for $N = 100$ and 200 , we have

$$N = 100: \quad e \approx 2.718296147450418,$$

$$E(0.01) = 1.431899137260828 \times 10^{-5}$$

and

$$N = 200: \quad e \approx 2.718285408211362,$$

$$E(0.005) = 3.579752316795748 \times 10^{-6},$$

and, therefore,

$$\frac{E(0.01)}{E(0.005)} = 3.999995001169598 \approx 2^2 = 4,$$

as predicted by the theoretical formula. An improved numerical algorithm for integration is the composite Simpson's rule, defined as

$$e = \frac{h}{3} \left(f(0) + 4 \sum_{n=1}^{N/2} f(h(2n-1)) \right. \\ \left. + 2 \sum_{n=1}^{N/2-1} f(2hn) + f(1) \right) + E(h),$$

where the theoretical truncation error is $E(h) = \alpha_4 h^4$ and N is even. The composite Simpson's rule converges to the integral as the fourth-order method. Indeed, computing the algorithm for $N = 100$ and 200 , we have

$$N = 100 : e \approx 2.718281828554504, \\ E(0.01) = 9.545830792490051 \times 10^{-11}$$

and

$$N = 200 : e \approx 2.718281828465013, \\ E(0.005) = 5.967226712755291 \times 10^{-12}$$

and, therefore,

$$\frac{E(0.01)}{E(0.005)} = 15.99709756642108 \approx 2^4 = 16,$$

as predicted by the theoretical formula.

Iteration Methods

Solutions of algebraic, differential, partial differential, and integral equations can be approximated with iteration methods. Numerical errors in iteration methods may grow during iterations. When this happens, numerical approximations cannot give the exact solution because instabilities lead to huge numerical errors. If the numerical iterations are unstable, it does not matter how accurately the truncation error converges to zero with smaller discretization step size. Propagation and growth of numerical errors can be illustrated with the linear iteration map:

$$x_{n+1} = qx_n, \quad |q| \geq 1.$$

The exact solution of the linear iteration map is $x_n = q^n x_0$, where x_0 is the starting value. If two iteration sequences are obtained from almost identical values $x_0^{(1)}$ and $x_0^{(2)}$, so the initial distance $e_0 = |x_0^{(1)} - x_0^{(2)}|$ is small, then the distance grows with larger n as $e_n = |q|^n e_0$. Two iteration sequences diverge from each other, even if the small error e_0 was generated by the round-off error!

Numerical instabilities and divergences often occur in solutions of algebraic equations, which represent the simplest numerical problems. A scalar algebraic equation $f(x) = 0$ can be reformulated as a root finding algorithm:

$$x_* : f(x_*) = 0.$$

If we plot $f(x)$ as a function of x , the root x_* can be immediately found from the graph $y = f(x)$, if it exists. Algorithmically, we can try to approximate the root x_* from the iteration method:

$$x_{n+1} = x_n + f(x_n).$$

If the limit $x_\infty = \lim_{n \rightarrow \infty} x_n$ exists, then the root x_* is a fixed point of the iteration method such that $x_\infty = x_*$.

If the limit x_∞ does not exist but x_* is known to exist, the numerical method fails and iterations $\{x_n\}_{n=1}^\infty$ diverge due to numerical instabilities. Analysis of convergence of the iteration method can be performed with the linearization of the iteration method. Let $e_n = x_n - x_*$ be the small distance of x_n from the fixed point x_* such that

$$e_{n+1} = x_n + f(x_n) - x_* = e_n + f(x_* + e_n) - f(x_*) \\ = qe_n + \alpha_n e_n^2, \quad q = 1 + f'(x_*),$$

where α_n is constant, such that $\lim_{n \rightarrow \infty} \alpha_n$ exists. If $|q| \geq 1$, the error e_n grows with larger n and iterations $\{x_n\}_{n=1}^\infty$ and $\{e_n\}_{n=1}^\infty$ diverge. In this case, the fixed point x_* cannot be found from the iteration method. For example, when $f(x) = 3x - 6$, the fixed point $x_* = 2$ cannot be found iteratively, since $q = 4 > 1$.

An improved iteration algorithm is Newton's method which approximates a new point x_{n+1} from the root of the tangent line to the graph $y = f(x)$ at the previous point x_n . Thus

$$0 = f(x_n) + f'(x_n)(x_{n+1} - x_n) + O(x_{n+1} - x_n)^2,$$

such that

$$x_{n+1} = x_n - \frac{f(x_n)}{f'(x_n)}.$$

Newton's method always converges to a fixed point x_* , if the fixed point x_* exists. The rate of convergence depends on whether the root $x = x_*$ is simple or multiple. For a single root when $f'(x_*) \neq 0$, the rate of convergence is quadratic in terms of the error e_n , since

$$q = \lim_{x \rightarrow x_*} \frac{f(x)f''(x)}{(f'(x))^2} = 0.$$

For a multiple root when $f(x) \sim (x - x_*)^m$ and $m > 1$, the rate of convergence is linear in terms of e_n , since $q = (m - 1)/m$. When the function $f(x)$ is linear as in the example $f(x) = 3x - 6$, the convergence of the Newton-Raphson method occurs in a single iteration, no matter what x_0 is

$$x_1 = x_0 - \frac{3x_0 - 6}{3} = 2 = x_*.$$

Differential Equations

Numerical algorithms are particularly attractive for solutions of differential equations, which are widely used in all areas of physics and engineering. It is especially important because many applied differential equations cannot be solved in terms of analytical functions. The simplest differential equation is given by a scalar first-order quasilinear equation:

$$\frac{dy}{dt} = f(t, y),$$

starting with the initial condition: $y(0) = y_0$. Since $y(0) = y_0$ and $y'(0) = f(0, y_0)$ are known, it makes sense to step from $t = 0$ along the tangent line to the curve $y = y(t)$ at the point $(0, y_0)$. Using a number of steps from $t = 0$ to T with small step size h , we define a numerical approximation of $y(t_n)$ as y_n , such that $y(t_n) = y_n + e_n$, where e_n is the numerical error, accumulated after n steps. If all steps are taken along the tangent line segments to the points (t_n, y_n) , we have the Euler method (also known as the slope approximation):

$$y_{n+1} = y_n + hf(t_n, y_n).$$

When the time $t = T$ is reached in N steps, such that $T = Nh$, the global error is defined as $E_T = |y(T) - y_N|$. The global error for the Euler method is theoretically given by $E_T = \alpha_1 h$, such that the Euler method is the least accurate, first-order method. Figure 1 shows that oscillations of the undamped pendulum in the nonlinear second-order equation:

$$y'' + \sin y = 0$$

are destroyed in Euler's method. The inaccurate Euler's method introduces an effective damping due to numerical discretization.

Numerical methods for differential equations also produce numerical instabilities. For example, the linear first-order equation for exponential decay:

$$\frac{dy}{dt} = -\lambda y, \quad \lambda > 0,$$

has a simple solution: $y(t) = y_0 e^{-\lambda t}$. Euler's method applied to this equation is equivalent to the linear iteration map:

$$y_{n+1} = (1 - \lambda h)y_n,$$

which diverges for $h > 2/\lambda$, when $|1 - \lambda h| > 1$. When $\lambda \rightarrow 0$, the differential equation for the exponential decay becomes stiff for numerical solution, since the step size h for numerical discretization must be very small to preserve stability of numerical approximation.

Advanced algorithms for numerical solutions of differential equations are developed with numerical integration methods. For example, integrating the first-order quasi-linear equation with the trapezoidal rule on the interval $t \in [t_n, t_{n+1}]$, we derive the implicit iteration method:

$$y_{n+1} = y_n + \frac{h}{2} [f(t_n, y_n) + f(t_{n+1}, y_{n+1})].$$

The global; truncation method of the method is $E_T = \alpha_2 h^2$, that is, it is the second-order method. The method is also implicit since the unknown values of y_{n+1} appear at the left and right sides of the equation. The implicit methods can be solved with iterations at each n , by means of root finding

Figure 1. Oscillations of the undamped pendulum in Euler's and Heun's numerical methods.

algorithms. However, this modification makes the algorithm complicated and time-consuming. Predictor-corrector methods are used instead, either with single-step (Runge–Kutta) methods or with multi-step (Adams–Bashforth–Moulton) methods. For example, the second-order Runge–Kutta method (also known as the Heun's or improved Euler's method) is based on the trapezoidal rule in the form

$$p_{n+1} = y_n + hf(t_n, y_n),$$

$$y_{n+1} = y_n + \frac{h}{2} [f(t_n, y_n) + f(t_{n+1}, p_{n+1})],$$

where p_{n+1} is the predicted value at $t = t_{n+1}$ by using the slope approximation and y_{n+1} is the corrected value at $t = t_{n+1}$ by using the trapezoidal rule. The predictor-corrector method above has the same global truncation error $E_T = \tilde{\alpha}_2 h^2$ with a different numerical constant $\tilde{\alpha}_2$. Figure 1 shows that oscillations of the undamped pendulum are well preserved in the Heun's method based on predictions and corrections.

The most popular and accurate method is the fourth-order Runge–Kutta method, which takes four computations of the function $f(t, y)$ for a single step from $t = t_n$ to $t = t_{n+1}$ and has the global truncation error $E_T = \alpha_4 h^4$.

Higher-order predictor-corrector methods are still affected by numerical instabilities, especially in the case of stiff differential equations. More reliable methods for stiff problems are based on implicit integration formulas. Implicit methods can be rewritten as explicit methods if the function $f(t, y)$ is linear in y . For example, the equation for the exponential decay can be integrated with the implicit second-order method based on the trapezoidal rule, as follows:

$$y_{n+1} = \frac{2 - h\lambda}{2 + h\lambda} y_n.$$

Since $|(2 - h\lambda)/(2 + h\lambda)| \leq 1$ for any h and $\lambda > 0$, the implicit method is unconditionally stable, no matter how large the step size h is chosen. The accuracy of the method is still the same as in the second-order Heun's method, so the step size h must not be too large, to preserve accuracy of numerical approximation.

Partial Differential Equations

Partial differential equations are defined in two- and higher-dimensional domains. They represent most complicated and time-consuming problems for numerical methods. Initial values for partial differential equations at time $t = 0$ are supplemented by boundary values at the boundaries of a physical domain. A simple example of a linear partial differential equation is given by the heat equation, derived for a one-dimensional rod of finite length L :

$$\frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial x^2} + f(x, t), \quad 0 < x < L, \quad t > 0,$$

such that

$$u(0, t) = u_0(t), \quad u(L, t) = u_L(t), \quad u(x, 0) = \phi(x).$$

The heat equation describes temperature $u(x, t)$ as function of time $t \geq 0$ and the point $0 \leq x \leq L$ in the rod. The heat sources $f(x, t)$, temperature values at the end points $u_0(t)$ and $u_L(t)$ and initial temperature $\phi(x)$ are all given as physical parameters of the problem. In the finite-difference methods, numerical approximations of $u(x, t)$ are defined at the equally spaced numerical grid with points at $x_n = nh, n = 0, 1, \dots, N$, where h is the step size, such that $L = Nh$. Numerical approximations of $u(x, t)$ are also evaluated with equal time step τ at points $t_k = k\tau, k = 0, 1, \dots$. Denoting $u_{n,k}$ as numerical approximation of $u(x_n, t_k)$, we approximate the second x -derivative of $u(x, t)$ by the central difference, derived from Taylor series expansions:

$$\begin{aligned} u_{n+1,k} &= u_{n,k} + hu_x(x_n, t_k) + \frac{1}{2}h^2u_{xx}(x_n, t_k) \\ &\quad + \frac{1}{3!}h^3u_{xxx}(x_n, t_k) + O(h^4), \\ u_{n-1,k} &= u_{n,k} - hu_x(x_n, t_k) + \frac{1}{2}h^2u_{xx}(x_n, t_k) \\ &\quad - \frac{1}{3!}h^3u_{xxx}(x_n, t_k) + O(h^4), \end{aligned}$$

such that

$$\frac{\partial^2 u}{\partial x^2}(x_n, t_k) = \frac{u_{n+1,k} - 2u_{n,k} + u_{n-1,k}}{h^2} + O(h^2).$$

Using the slope approximation, we perform the time step from $u_{n,k}$ to $u_{n,k+1}$ according to the explicit finite-difference scheme:

$$u_{n,k+1} = (1 - 2r)u_{n,k} + r(u_{n+1,k} + u_{n-1,k}) + \tau f_{n,k},$$

where $r = \tau/h^2, n = 1, \dots, N - 1$, and $k = 0, 1, \dots$. All boundary and initial values $u_{0,k}, u_{N,k}$ and $u_{n,0}$ are incorporated in computations of the explicit method for $n = 1, N - 1$, and $k = 0$. Numerical approximations of $u_{n,k}$ are only computed at internal points of the

Figure 2. Solutions of the heat equation with the explicit method.

grid. The total error of the explicit method is a composition of the truncation error of order $O(h^2)$ for the central difference approximation and the truncation error of order $O(\tau)$ for the Euler's method. The explicit method is least accurate with respect to time step size τ . It is also an unstable method for $r > 0.5$ when $\tau > h^2/2$. Figure 2 shows numerical solution of the heat equation with the explicit method for $f(x, t) = 0, u_0 = u_L = 0, \phi = \sin(\pi x), L = 2, h = 0.1$, and $r = 0.55$. Development of instabilities of the explicit method destroys validity of the numerical approximations.

Implicit methods are more reliable in numerical computations. The implicit method, which is based on the trapezoidal rule of integration, is referred to as the Crank–Nicholson method. The method results in a linear system of equations:

$$\begin{aligned} A(r)\mathbf{u}_{k+1} &= A(-r)\mathbf{u}_k + \frac{\tau}{2}(\mathbf{f}_k + \mathbf{f}_{k+1}) \\ &\quad + \frac{r}{2}(\mathbf{b}_k + \mathbf{b}_{k+1}), \quad k \geq 0, \end{aligned}$$

where

$$\mathbf{u}_k = \begin{bmatrix} u_{1,k} \\ u_{2,k} \\ \vdots \\ u_{N-2,k} \\ u_{N-1,k} \end{bmatrix}, \quad \mathbf{f}_k = \begin{bmatrix} f_{1,k} \\ f_{2,k} \\ \vdots \\ f_{N-2,k} \\ f_{N-1,k} \end{bmatrix},$$
$$\mathbf{b}_k = \begin{bmatrix} u_{0,k} \\ 0 \\ \vdots \\ 0 \\ u_{N,k} \end{bmatrix}$$

and

$$A(r) = \begin{bmatrix} 1+r & -r/2 & 0 & \cdots & 0 \\ -r/2 & 1+r & -r/2 & \cdots & 0 \\ 0 & -r/2 & 1+r & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1+r \end{bmatrix}.$$

Although solving of the linear system at each time step is a time-consuming operation, the Crank–Nicholson

Figure 3. Solutions of the heat equation with the Crank-Nicholson method.

method is more useful compared with the explicit method. In particular, the method has a symmetric numerical error $O(\tau^2 + h^2)$ and unconditional numerical stability for any $\tau > 0$. Figure 3 shows numerical solution of the heat equation with the Crank-Nicholson method for $h = 0.1$ and $r = 1$ when $\tau = h^2$. The numerical solution is stable in time evolution.

Finite-difference methods are used successfully in numerical solution of other boundary-value problems for partial differential equations. Explicit methods have a very straightforward form. Implicit methods are unconditionally stable and result in linear systems for linear differential equations. Implicit methods are usually replaced by the semi-implicit algorithms for nonlinear differential equations. As a drawback, finite-difference methods have low accuracy. More advanced (and also more involved) shooting, finite-element, and spectral methods are used for improved solutions of boundary-value problems.

Shooting methods are based on transformations of the boundary-value problems into the initial-value problems, which are iterated with the root finding algorithms. For simplicity, we illustrate with ordinary differential equations, although multi-dimensional shooting methods are also applied to partial differential equations. We consider a numerical approximation of radially symmetrical bound states of the two-dimensional nonlinear Schrödinger equations, which satisfy the boundary-value problem:

$$\frac{d^2\Phi}{dr^2} + \frac{1}{r} \frac{d\Phi}{dr} - \Phi + 2\Phi^3 = 0, \quad 0 < r < R,$$

such that

$$\Phi'(0) = 0, \quad \Phi(R) = 0,$$

where R is large length of the approximation interval. Using a shooting numerical method, we consider a solution of the initial-value problem for the same equation $\Phi = \Phi_m(r)$, such that

$$\Phi_m(0) = m, \quad \Phi'_m(0) = 0,$$

where the value of m is unknown. Solving the differential equation on $r \in [0, R]$ with an appropriate

Figure 4. Bound state of the nonlinear Schrödinger equation with the numerical shooting method: starting (dotted) and final (solid) approximations.

numerical method, such as the fourth-order Runge-Kutta method, we define the function of parameter m as

$$E(m) = \Phi_m(R).$$

The function $E(m)$ has a zero at $m = m_*$ if $\Phi_{m_*}(r)$ is the bound state of the nonlinear Schrödinger equation, such that $\Phi_{m_*}(R) = 0$. Starting with any value m_0 , we can approach to the zero of $E(m)$ with a root finding algorithm, such as the Newton's method:

$$m_{k+1} = m_k - \frac{E(m_k)}{E'(m_k)},$$

where the value of

$$E'(m_k) = \left. \frac{\partial \Phi_m(R)}{\partial m} \right|_{m=m_k}$$

can be found from a linearization problem or from a secant method. The starting approximation $\Phi_{m_0}(r)$ and the final solution $\Phi_{m_*}(r)$ are shown on Figure 4 by dotted and solid lines, respectively. The value of $E(m_k)$ converges to zero, such that the sequence $\Phi_{m_k}(r)$ converges to the bound state $\Phi(r)$ of the nonlinear Schrödinger equation.

Finite-element methods approximate solutions of the boundary-value problems from a variational problem, which involves minimization of the energy functionals. The bound state $\Phi(r)$ of the nonlinear Schrödinger equation coincides with a minimizer of the energy functional:

$$H(u) = \frac{1}{2} \int_0^R \left[\left(\frac{du}{dr} \right)^2 - u^4 \right] r dr,$$

such that the variation of $H(u)$ vanishes if and only if $u = \Phi(r)$:

$$\left. \frac{\delta H}{\delta u} \right|_{u=\Phi(r)} = -\frac{d}{dr} \left[r \frac{d\Phi}{dr} \right] - 2r\Phi^3 = 0.$$

Dividing the interval $r \in [0, R]$ into n subintervals $[0, r_1] \cup [r_1, r_2] \cup \dots \cup [r_{N-1}, r_N]$, where $r_n = hn$ and $R = hN$, we approximate $\Phi(r)$ by a linear combination

of the finite elements $u_n(r)$:

$$u(r) = \sum_{n=0}^N \Phi_n u_n(r).$$

The finite elements $u_n(r)$ satisfy the constraints:

$$u_n(r_n) = 1, \quad \text{and} \quad u_n(r_m) = 0, \quad m \neq n,$$

such that Φ_n are unknown values for the finite-element approximation of $u(r_n)$. The simplest finite elements (also known as the simplex elements) are given by the piecewise linear interpolation:

$$u_n(r) = \begin{cases} 0, & r \leq r_{n-1}, \\ \frac{r-r_{n-1}}{h}, & r_{n-1} \leq r \leq r_n, \\ \frac{r_{n+1}-r}{h}, & r_n \leq r \leq r_{n+1}, \\ 0, & r \geq r_{n+1}. \end{cases}$$

When $u(r)$ is substituted into the energy functional $H(u)$ and integrated numerically over $0 \leq r \leq R$, the function $H(u) = H(\Phi_0, \Phi_1, \dots, \Phi_{N-1})$ with $\Phi_N = 0$ can be minimized with respect to parameters $\Phi_0, \Phi_1, \dots, \Phi_{N-1}$. The minimization leads to a system of nonlinear algebraic equations:

$$\frac{\partial H(u)}{\partial \Phi_n} \equiv h_n(\Phi_0, \Phi_1, \dots, \Phi_{N-1}) = 0, \\ n = 0, 1, \dots, N-1.$$

This nonlinear system can be solved with a matrix root finding Newton's method, which completes the finite-element approximation of the bound states $\Phi(r)$. When the differential equations are linear and the exact integrations are replaced with the trapezoidal rule, the finite-element method with simplex elements recovers the finite-difference approximation. However, the finite-element method is more general and suitable for accurate numerical approximations. For example, the finite-element method can be used together with the Simpson's rule of numerical integration.

Spectral methods are based on Fourier series solutions of differential equations in finite intervals, subject to appropriate boundary conditions. Solutions of the homogeneous heat equation $u_t = u_{xx}$ on $x \in [0, L]$ with zero boundary conditions at the ends: $u(0, t) = u(L, t) = 0$ are given by the Fourier sine-series:

$$u(x, t) = \sum_{m=1}^{\infty} B_m(t) \sin \frac{\pi m x}{L},$$

where the set of Fourier amplitudes $B_m(t)$, $m \geq 1$ solves the initial-value problems:

$$\frac{dB_m}{dt} = -\frac{\pi^2 m^2}{L^2} B_m, \quad m \geq 1.$$

The initial values of $B_m(0)$ are defined from $u(x, 0)$ by the Fourier integrals:

$$B_m(0) = \frac{2}{L} \int_0^L u(x, 0) \sin \frac{\pi m x}{L} dx.$$

Truncating the Fourier series with the Galerkin method and defining the Fourier approximation at grid points $x_n = nh$, $n = 1, \dots, N-1$, we replace the exact Fourier series solution with the discrete Fourier transform:

$$u(x_n, t) = \sum_{m=1}^{N-1} B_m(t) \sin \frac{\pi m n}{N},$$

where $B_m(t)$ solves the same initial-value problem for $m = 1, \dots, N-1$ but $B_m(0)$ is defined by the inverse discrete Fourier transform:

$$B_m(0) = \frac{2}{N} \sum_{n=1}^{N-1} u(x_n, 0) \sin \frac{\pi m n}{N}.$$

We notice that the inverse discrete Fourier transform follows from Fourier integrals by means of the numerical trapezoidal rule. Solving systems of initial-value problems with Runge-Kutta methods, we define solutions of the heat equation at time steps $t_k = k\tau$, $k = 0, 1, \dots$

Spectral methods give more accurate solutions of the heat equation, compared with the finite-difference methods. First, all initial-value problems for Fourier coefficients $B_m(t)$ are uncoupled. Second, the spectral methods have superior accuracy, because the truncation error of the Galerkin approximation decays exponentially with larger number N of the Fourier amplitudes. Third, spectral methods can be applied to nonlinear differential equations. Performing time steps with the Runge-Kutta methods, discrete Fourier transform and its inverse can be employed for computations of the nonlinear terms. As a result, the spectral method is effectively uncoupled for Fourier amplitudes $B_n(t)$ as an explicit single-step method. Split-step spectral methods are especially important for nonlinear evolution equations, such as the nonlinear Schrödinger equations.

As computational power increases, the role of numerical methods will be increasingly important in coming years for efficient solutions of many problems in physical and engineering sciences. Presently, computations of three-dimensional equations for water waves, turbulence, and astrophysical problems can be run on workstations in reasonable time. Modern supercomputing resources based on multiprocessor clusters are designed to help scientists in their theoretical studies of nature. It is common nowadays that many research groups in physics and engineering replace analysis of a problem by numerical methods.

N-WAVE INTERACTIONS

Linear dispersive waves propagate according to a dispersion relation

$$\omega = \omega(\mathbf{k}),$$

which relates the frequency ω to the wave vector $\mathbf{k}$. In linear systems, waves of different wave vectors and frequencies do not interact due to the superposition principle. In nonlinear systems, the lowest-order nonlinear effect (expanding in the wave amplitudes) is the interaction between N waves of different wave vectors $\mathbf{k}_j$ and frequencies ω_j , which satisfy the spatial and temporal resonance conditions (Zaslavsky & Sagdeev, 1988)

$$\sum_{j=1}^N \mathbf{k}_j = \mathbf{0}, \quad \sum_{j=1}^N \omega(\mathbf{k}_j) = 0.$$

The simplest three-wave resonant interaction occurs if there are nontrivial solutions with

$$\mathbf{k} = \mathbf{k}_1 + \mathbf{k}_2, \quad \omega(\mathbf{k}) = \omega(\mathbf{k}_1) + \omega(\mathbf{k}_2). \quad (1)$$

Resonant wave interactions are governed by the dispersion relation. Some dispersion relations do not exhibit nontrivial solutions of the resonance conditions (1) for any $\mathbf{k}_1$ and $\mathbf{k}_2$. Others may exhibit resonant three-wave interactions, for example the deep-water gravity-capillary waves satisfying the dispersion relation $\omega^2(\mathbf{k}) = g|\mathbf{k}| + T|\mathbf{k}|^3$, where g is the acceleration of gravity and T is the surface tension coefficient. When $T \neq 0$, the resonant configurations of the three waves occur already in one spatial dimension, as shown on a graphical solution on Figure 1. The solid curve on this figure shows the dispersion relation $\omega = \omega(k)$, while the dashed curve shows the same dispersion relation shifted relatively to the point (k_1, ω_1) , such that $\omega - \omega_1 = \omega(k - k_1)$ and $\omega_1 = \omega(k_1)$. The intersection of the two curves defines a solution of the resonance equations (1) at the point $k = k_1 + k_2$, where $\omega(k) - \omega(k_1) = \omega(k_2)$.

When $T = 0$, the resonant three-wave configurations do not occur in space of any dimensions, but deep-water gravity waves satisfying the dispersion relation $\omega^2 = g|\mathbf{k}|$ exhibit the resonant four-wave interactions of the following type:

$$\mathbf{k}_1 + \mathbf{k}_2 = \mathbf{k}_3 + \mathbf{k}_4,$$

$$\omega(\mathbf{k}_1) + \omega(\mathbf{k}_2) = \omega(\mathbf{k}_3) + \omega(\mathbf{k}_4).$$

Figure 1. Graphical solution of Equations (1) for three resonant waves.

Given a dispersion relation $\omega(\mathbf{k})$ with one or more branches, one needs to compute all lowest-order resonances for $N = 3, 4$, and so on, in order to describe nonlinear dynamics of resonant wave interactions with the normal form analysis (Craig, 1996).

Time evolution of N resonant waves can be studied with an asymptotic multiscale expansion method. In this method, a solution of the system $u = u(\mathbf{x}, t)$ is assumed to be close to a linear superposition of N resonant waves with slowly varying amplitudes, where $\mathbf{x} = (x, y, z)$. For instance, resonant interaction of three waves is described by the following expansion (Gaponov-Grekhov & Rabinovich, 1992):

$$u(\mathbf{x}, t) = \varepsilon \left[a(\varepsilon \mathbf{x}, \varepsilon t) e^{i(\mathbf{k} \mathbf{x} - \omega(\mathbf{k})t)} + a_1(\varepsilon \mathbf{x}, \varepsilon t) e^{i(\mathbf{k}_1 \mathbf{x} - \omega(\mathbf{k}_1)t)} + a_2(\varepsilon \mathbf{x}, \varepsilon t) e^{i(\mathbf{k}_2 \mathbf{x} - \omega(\mathbf{k}_2)t)} \right],$$

where ε is a small parameter and ε^2 terms are dropped. The evolution equations for the wave amplitudes take the form

$$\begin{aligned} i \left(\frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla \right) a &= \gamma a_1 a_2 e^{-i\Delta t}, \\ i \left(\frac{\partial}{\partial t} + \mathbf{v}_1 \cdot \nabla \right) a_1 &= \gamma_1 a \bar{a}_2 e^{i\Delta t}, \\ i \left(\frac{\partial}{\partial t} + \mathbf{v}_2 \cdot \nabla \right) a_2 &= \gamma_2 a \bar{a}_1 e^{i\Delta t}. \end{aligned} \quad (2)$$

Here $\Delta = \omega(\mathbf{k}) - \omega(\mathbf{k}_1) - \omega(\mathbf{k}_2)$ is the frequency detuning from the exact resonance; $\mathbf{v}$, $\mathbf{v}_1$, and $\mathbf{v}_2$ are group velocities of the three waves, for example $\mathbf{v} = \nabla \omega(\mathbf{k})$; and γ , γ_1 , and γ_2 are coupling coefficients in systems with quadratic nonlinearities. In nonlinear dispersive systems with conserved energy, parameters γ , γ_1 , and γ_2 are real.

Typical dynamics of the resonant three-wave interaction can be studied from system (2) for space-

Figure 2. Two typical time evolutions of the three-wave resonant interaction: (a) the high-frequency wave a could not be generated from large low-frequency wave a_1 and small low-frequency wave a_2 ; (b) the large high-frequency wave a decays into pair of low-frequency waves a_1 and a_2 .

independent waves $a(t)$, $a_1(t)$, and $a_2(t)$ in the case of exact resonance, when $\Delta = 0$. Without loss of generality, the real coupling coefficients can be normalized to be equal and positive: $\gamma = \gamma_1 = \gamma_2 > 0$. After these simplifications, system (2) has the following (Manley–Rowe) constants of motion:

$$\begin{aligned} |a|^2 + |a_1|^2 &= C_1, & |a|^2 + |a_2|^2 &= C_2, \\ |a_1|^2 - |a_2|^2 &= C. \end{aligned} \quad (3)$$

The time evolution of wave amplitudes $a(t)$, $a_1(t)$, and $a_2(t)$ displays two typical scenarios shown in Figure 2(a,b). If the wave with low frequency ($\omega_1, \omega_2 < \omega$) is initially pumped into the system (e.g., either $|a_1|^2 \gg |a|^2, |a_2|^2$ or $|a_2|^2 \gg |a|^2, |a_1|^2$ at $t = 0$), then the other two resonant waves remain small throughout the whole time evolution (see Figure 2(a)). Indeed, it is seen from Equations (3) that when $|a|^2$ grows, $|a_1|^2$ and $|a_2|^2$ decay. If either $|a_1|^2$ or $|a_2|^2$ were initially small, their decay (and the growth of $|a|^2$) is limited by a small value of C_1 and C_2 .

If the wave of high frequency ω is initially pumped, however, the waves of low frequencies ω_1 and ω_2 may grow simultaneously. In this case, the resonant three-wave interactions display an exchange of energy between the high-frequency wave and the two low-frequency waves (see Figure 2(b)). This process is referred to as the “splitting” or “decaying” instability of the high-frequency wave. As seen from system (2) for small a_1 and a_2 , the amplitude $a(t)$ does not change in time in the first-order approximation, while amplitudes $a_1(t)$ and $a_2(t)$ grow exponentially as $\sim e^{\gamma a |t|}$. The high-frequency wave $|a|^2$ decays into the two low-frequency waves $|a_1|^2$ and $|a_2|^2$, but the two waves merge back to the high-frequency wave later in the time evolution (see Figure 2(b)).

Resonant nonlinear three-wave interactions are known in many physical situations, such as in water waves, nonlinear optics, acoustics, and plasma physics. In nonlinear optics, resonant three-wave interactions are used in parametric amplifiers and oscillators, $\chi^{(2)}$ optical materials, self-induced transparency, and stimulated Raman scattering (Kaup et al., 1977). Four-wave mixing occur in optical communications and leads to growth of ghost pulses in an optical signal sequence. In water waves, resonant wave interactions explain effects of weak turbulence of gravity and gravity-capillary waves, as well as Rossby waves in the atmosphere (Zakharov, 1998). In plasma physics, nonlinear dynamics of high-temperature plasmas in a magnetic fields involve wave-particle and wave-wave interactions. Resonant three-wave interactions occur in ionospheric propagation, plasma heating with high-power electromagnetic sources, microwave sources, and laser sources (Kaup et al., 1977).

ONE-DIMENSIONAL MAPS

The term *one-dimensional map* usually indicates a dynamical system with discrete time, generated by some map f of a one-dimensional (1-d) space (the real line or an interval of it, a circle, or a graph) onto itself or, equivalently, the iterations of this map. To specify a 1-d space, the terms *interval map*, *circle map*, or *graph map* are used. The most famous examples of a 1-d maps are the so-called logistic map $x \mapsto \lambda x(1-x)$ of the interval $[0, 1]$ and the rotation $x \mapsto x + \alpha$ of the circle. The theory of 1-d maps can also be considered as the qualitative theory of the difference equations of the form $x_{n+1} = f(x_n)$, $n = 0, 1, 2, \dots$.

Being part of the general theory of dynamical systems, the theory of 1-d maps includes studies relating to topological dynamics, symbolic dynamics, combinatorial dynamics, differential (or smooth) dynamics, and ergodic theory. The theory of 1-d maps is well developed and contains many deep and beautiful results. Even the simplest non-invertible (for example, quadratic) 1-d maps possess orbits with intricate dynamics, including those behaving like random processes. Thus, this theory offers comparatively simple tools for the understanding of general laws that govern the progression of real dynamic processes from regular to chaotic behaviors.

Many mathematical models, including those arising in population biology, can be reduced to investigations of 1-d maps. For organisms with non-overlapping generations, the population growth can be modeled with the difference equation $x_{n+1} = f(x_n)$, where x_n is the population density of the n th generation. When the density of the population is small and there are plenty of resources, the density x_n increases and follows approximately the linear law $x_{n+1} = \lambda x_n$, where λ is the reproduction coefficient. Because resources are bounded, density cannot increase forever; moreover, if the density x_n is very large, that is, close to 1, then x_{n+1} —the density of the next generation—must be close to 0. The logistic function $f(x) = \lambda x(1-x)$ with $0 < \lambda \leq 4$ is a canonical example.

Interval Maps

Let $f: J \rightarrow J$ be a map of the interval J onto itself and f^n be its iterations, defined by $f^n(x) = f(f^{n-1}(x))$, $n = 1, 2, \dots$, $f^0(x) = x$. The orbit of a point $x_0 \in J$ under the map f is the sequence of points $x_n = f^n(x_0)$, $n = 0, 1, 2, \dots$.

A point $\beta \in J$ is a periodic point if $f^m(\beta) = \beta$ for some natural m ; the smallest m with this property is the *period* of β ; if $m = 1$, β is called a fixed point. The points $f^n(\beta)$, $n = 0, 1, \dots, m-1$ form a cycle of period m . To characterize the asymptotic behavior of an orbit, the set of its limiting points is used; it is called the ω -limit set of the orbit of x and denoted by $\omega(x)$. A cycle B is attracting if there exists a neighborhood U of B such that for any $x \in U$, $f^n(x) \in U$ for all $n > 0$ and $\omega(x) = B$. The basin of an attracting cycle B is the set $\{x \in J : \omega(x) = B\}$; it consists of a finite or countable number of (open) intervals. A cycle B is repelling if there exists a neighborhood U of B such that for any point $x \in U \setminus B$, there exists n such that $f^n(x) \notin U$. If f is differentiable and has a cycle $B = \{\beta_1, \dots, \beta_m\}$, the quantity $\mu(B) = f'(\beta_1) \cdot \dots \cdot f'(\beta_m)$ is the multiplier of B . B is attracting if $|\mu(B)| < 1$, and B is repelling if $|\mu(B)| > 1$. The smallest closed set that contains ω -limit sets of orbits for almost all points of J (with respect to Lebesgue measure), is called the (global) attractor of f and denoted by A below.

If f is a monotonic (and hence, invertible) continuous function, its dynamics are very simple. If f is monotonically increasing, the ω -limit set of each orbit consists of only a fixed point. If f is monotonically decreasing, the ω -limit set of each orbit is either a fixed point or a cycle of period 2.

The orbits of nonmonotonic (non-invertible) maps can be very complicated. Maps with a single extremum point are called unimodal. Many properties of continuous interval maps can be demonstrated with the simplest representative of unimodal maps—the family of logistic maps $f: x \mapsto \lambda x(1-x)$.

Figure 1. This Königs-Lamerey diagram gives a graphic representation of the orbit of x_0 . If the graphs of two functions $y = f(x)$ and $y = x$ in the plane (x, y) are drawn, then the broken line consisting of vertical and horizontal segments that connect the points $(f^n(x_0), f^n(x_0))$ and $(f^n(x_0), f^{n+1}(x_0))$, $n = 0, 1, 2, \dots$, demonstrates the movement along the orbit. The orbit of x'_0 tends to a fixed point, and the orbit of x''_0 tends to a cycle of period 3.

Figure 2. Bifurcation diagram of the attractors for the family of logistic maps.

Logistic Maps

The bifurcation diagram in Figure 2 shows what attractors the logistic map has when the parameter λ is changed.

With increasing λ up to $\lambda^* \approx 3.5699$, the consecutive doubling of period for attracting cycles holds and cycles of periods 2^n , $n = 0, 1, 2, \dots$, appear: when $\lambda > 3$, the attracting fixed point $\beta_1 = 1 - 1/\lambda$ becomes repelling and a new attracting cycle of period 2 arises; for $\lambda > 1 + \sqrt{6} = 3.449 \dots$, this cycle becomes repelling and generates an attracting cycle of period 4, and so on. The period doubling for attracting cycles occurs with the speed

$$\frac{\lambda_{2^{n+1}} - \lambda_{2^n}}{\lambda_{2^{n+2}} - \lambda_{2^{n+1}}} \rightarrow 4.6692 \dots$$

(Feigenbaum-Coullet-Tresser constant), where λ_{2^n} is the parameter value when the cycle of period 2^n arises. The basin of each such attracting cycle is the

interval $J = [0, 1]$ except for a countable set of repelling periodic points and their preimages.

If $\lambda = \lambda^*$, f has cycles of periods 2^n , $n = 0, 1, 2, \dots$, only, and these cycles are repelling. The set K of limiting points for these cycles is an invariant Cantor set. The orbit of each point from K is everywhere dense on K . K is the attractor: the ω -limit set of each point from J , different from a periodic point or its preimages, coincides with K . The restriction of f^2 on the interval $[f^{-1}(\beta_1), \beta_1]$ is topologically conjugate to f on J , and hence, f is infinitely renormalizable.

For $\lambda = 3.83$, f has an attracting cycle of period 3, which is the attractor, and repelling cycles of all periods. The basin of the attracting cycle is J except for a Cantor set. This Cantor set is the closure of the set consisting of points of repelling cycles and their preimages.

If $\lambda = 4$, f is topologically expanding: for any interval $\tilde{J} \subset J$, there exists a number $m = m(\tilde{J})$ such that $f^m(\tilde{J}) = J$. Therefore, f has the property of sensitive dependence on initial conditions (sometimes called the "butterfly effect"). J is an attractor; periodic points lie everywhere dense on J . The map is topologically conjugate to the piecewise linear map

$$g : x \mapsto g(x) = \begin{cases} 2x, & 0 \leq x \leq 1/2, \\ 2(1-x), & 1/2 < x \leq 1 \end{cases}$$

with the help of $h(x) = (2/\pi) \arcsin \sqrt{x}$. Because the Lebesgue measure is invariant under g , f has the invariant measure $\nu(dx) = dh(x) = \frac{1}{\sqrt{x}} dx / \sqrt{x(1-x)}$. This means, in particular, that for almost every orbit of f and for any $a_1, a_2 \in [0, 1]$, the frequency with which the orbit visits the interval (a_1, a_2) to $\int_{a_1}^{a_2} \nu(dx)$.

The general characteristics of the logistic maps family are formulated as follows: for each $\lambda \in [0, 4]$, the attractor $\mathbf{A}$ of f is a cycle, or a Cantor set (as in the case $\lambda = \lambda^*$), or a cycle of intervals, that is, several closed non-intersecting intervals J_n , $n = 1, \dots, m$, such that $f(J_n) = J_{(n+1) \bmod m}$ and $\bigcup_{n=1}^m J_n$ contain an everywhere dense orbit (in case $\lambda = 4$, $m = 1$).

The parameter values for which $\mathbf{A}$ is a cycle form an open and dense (on $[0, 4]$) set, and from the topological standpoint, a map with an attracting cycle is typical for the logistic family. The set of λ for which $\mathbf{A}$ is a Cantor set (and the map is infinitely renormalizable) has Lebesgue measure zero. The set of λ for which $\mathbf{A}$ is a cycle of intervals has positive Lebesgue measure. Moreover, for almost all value of these λ , $\mathbf{A}$ is the support of an ergodic absolutely continuous invariant measure.

The complication of dynamics in the logistic family stems, first of all, from the appearance of new attracting cycles resulting from the period-doubling bifurcation or the tangent bifurcation. With increasing λ , the multiplier of arising attracting cycle decreases from $+1$ to -1 , and thereafter, this cycle becomes repelling and does not disappear in the sequel. If λ_m denotes the infimum (greatest lower bound) of the parameter

values for which f has an attracting cycle of period m , then $\lambda_{m'} < \lambda_m$ for $m' < m$, where “ $<$ ” is the following ordering of the natural numbers:

$$1 < 2 < 2^2 < \dots < 2^n < \dots < 7 \cdot 2^n < 5 \cdot 2^n \\ < 3 \cdot 2^n < \dots < 9 < 7 < 5 < 3,$$

called “Sharkovsky’s ordering.” For $\lambda = \lambda_{2^n}$, $n > 0$, the cycle of period 2^n arises as a result of a period-doubling bifurcation; for $\lambda = \lambda_m$, $m \neq 2^n$, $n = 1, 2, \dots$, the cycle of period m arises as a result of a tangent bifurcation.

If f has an attracting cycle of period m , then with increasing λ , the sequence of period-doubling bifurcations takes place until cycles of periods 2^m , $n = 1, 2, \dots$, appear. For the limiting parameter value for this sequence of bifurcation values, the attractor is a Cantor set (as in the case $\lambda = \lambda^*$).

Smooth Maps

Analytic unimodal maps (briefly, AU-maps) and C^3 -smooth unimodal maps with negative Schwarzian

$$Sf = f'''/f' - \frac{3}{2} (f''/f')^2 \quad (1)$$

(briefly, SU-maps) are the most investigated classes of smooth maps. Any logistic map has negative Schwarzian.

As for logistic maps, the attractor $\mathbf{A}$ of each AU-map or SU-map includes (in general, not coincides with) one of the previous set: an (attracting) cycle, a Cantor set, or a cycle of intervals and always contains the ω -limit set of the extremum point. For an SU-map, $\mathbf{A}$ can have, in addition, only one attracting fixed point, and for an AU-map, $\mathbf{A}$ can have, in addition, any finite number of attracting cycles. If $\mathbf{A}$ is a cycle or a cycle of intervals, outside of $\mathbf{A}$, f has only a finite number of isolated repelling cycles and isolated repelling invariant Cantor sets.

The period-doubling and tangent bifurcations are typical for smooth maps. The birth order of attractive cycles for the logistic family is kept, for example, for families of convex SU-maps of the form $\lambda f(x)$, $\lambda > 0$.

For almost all members of a typical family of SU-maps, the attractor is either a cycle or a cycle of intervals; the cycle of intervals is the support of an ergodic absolutely continuous invariant measure; and there is a closed invariant interval $\hat{J} \subset J$ containing the extremum point and $m > 0$ such that the restriction of f^m on $\hat{J}$ is topologically conjugated to some logistic map.

For a typical family of AU-maps, there exists an open and dense set of parameters for which the map attractor consists of a finite number of cycles, and the union of basins of these cycles has full Lebesgue measure.

A smooth (at least C^2) unimodal map f is structurally stable if an attractor consists of cycles; the multiplier of each cycle is not equal to ± 1 ; the extremum point c is nondegenerate (i.e., $f''(c) \neq 0$); and $f^n(c)$ is not a periodic point for any $n = 0, 1, 2, \dots$

The class of structurally stable maps is open in the C^2 topology and dense in any smooth topology.

Some properties of unimodal maps (possibly somewhat modified) hold for maps with more than two branches of monotonicity. For example, the number of attracting cycles for any C^3 -smooth map with negative Schwarzian is not greater than the number of extremum points plus two.

Continuous Maps

Due to the natural ordering of points on the real line and the continuity of f , the values of f on a finite set of points provides rich information about the behavior of orbits. So, if there exist points $\beta_1 < \beta_2 < \beta_3$ such that $f(\beta_1) = \beta_1$, $f(\beta_2) = \beta_3$, and $f(\beta_3) \leq \beta_1$, then f has cycles with any period.

Each finite set $B = \{\beta_1 < \beta_2 < \dots < \beta_m\}$ such that $f(B) \subseteq B$ generates a permutation π on the set $\{1, 2, \dots, m\} : \pi(i) = j$, if $f(\beta_i) = \beta_j$, $i = 1, \dots, m$. If B is a cycle, such a permutation is cyclic. For $J_i = [\beta_i, \beta_{i+1}]$, $i = 1, 2, \dots, m-1$, $f(J_i) \supseteq J_{k(i)} \cup \dots \cup J_{K(i)}$, where $k(i) = \min\{\pi(i), \pi(i+1)\}$, $K(i) = \max\{\pi(i), \pi(i+1)\} - 1$. This allows the construction of a Markov matrix of admissible transitions with elements $a_{ij} : a_{ij} = 0$, if $f(J_i) \not\supseteq J_j$, and $a_{ij} = 1$, if $f(J_i) \supseteq J_j$, and the corresponding Markov graph. An analysis of loops of Markov graph allows us to obtain the Sharkovsky theorem on the cycles coexistence: if a continuous interval map has a cycle of period m , then it has a cycle of any period m' such that $m' < m$.

Research on the coexistence of combinatorial objects, such as cycles, permutations, cyclic permutations, and graphs, is the subject of combinatorial dynamics. An important part of symbolic dynamics for 1-d maps is the kneading theory.

There are different criteria for the chaotic behavior of orbits. In particular, the following properties are equivalent: (i) the *topological entropy* of f is positive; (ii) there is a cycle with period $\neq 2^n$, $n \geq 0$; (iii) there is a *homoclinic orbit*; (iv) there is an ω -limit set containing a cycle, but different from it; and (v) there exist m and a closed invariant set $M \subset J$ such that the restriction of f^m on M is topologically conjugate to the *shift* on the *space of one-side sequences of two symbols*. Any of these involves the following: there is a continuum of many orbits such that for any two orbits $\{x'_n\}$ and $\{x''_n\}$, $\liminf_{n \rightarrow \infty} |x'_n - x''_n| = 0$, $\limsup_{n \rightarrow \infty} |x'_n - x''_n| > 0$.

If f has a cycle of intervals $\{J_1, J_2, \dots, J_m\}$, then f on $\hat{J} = \bigcup_{i=1}^m J_i$ is topologically expanding and has the property of the sensitive dependence on initial conditions, and the set of periodic points is everywhere dense on $\hat{J}$.

The typical behavior of continuous maps differs from that of smooth maps. In particular, in the space of continuous maps with C^0 -topology, the set of maps that have cycles of all periods contains an open and

dense subset. Moreover, almost every continuous (but nowhere differentiable!) interval map has infinitely many minimal Cantor sets that attract almost all orbits.

Discontinuous interval maps constitute another important class of 1-d maps, especially for applications including expanding interval maps and so-called interval exchange maps.

Circle Maps

Many of the properties of interval maps mentioned above are true for circle maps $f: S \rightarrow S$. Along with this, there are classes of circle maps with specific properties, for example, circle homeomorphisms semi-conjugated to rotation of S with rotation number α (corresponding to the discontinuous interval map: $\hat{f}: x \mapsto x + \alpha \bmod 1$). If α is a rational number, the attractor A consists of cycles; if α is irrational, A is a minimal set and coincides with S or a Cantor set. Bifurcations in a family of circle homeomorphisms are described by Farey's sequences.

Circle maps, semi-conjugated to the discontinuous interval map $f: x \mapsto kx \bmod 1$ with an integer $|k| > 1$, are called circle maps of degree k and represent a further important class of circle maps, including expanding circle maps with $|f'(x)| > 1$ at $x \in S$. Any expanding map is topologically conjugate to the shift on the space of one-sided sequences of finite number of symbols; it is structurally stable and possesses an absolutely continuous invariant measure.

OPTICAL FIBER COMMUNICATIONS

The existence of temporal solitons in optical fibers and their use for optical communications were suggested in 1973 (Hasegawa & Tappert, 1973), and by 1980, such solitons had been observed experimentally (Mollenauer et al., 1980; Hasegawa & Kodama, 1995). Since then, rapid progress has converted temporal solitons into a practical candidate for designing modern communication systems based on optical-fiber technology (Agrawal, 2002; Kivshar & Agrawal, 2003).

Similar to other types of solitons, those in optical fibers emerge from a balance between the group-velocity dispersion (GVD) and self-phase modulation (SPM) induced by the Kerr nonlinearity. The GVD broadens optical pulses during their propagation inside an optical fiber, except when the pulse is initially chirped (compressed with linear frequency modulation) in the right way. More specifically, a chirped pulse can be compressed during the early stage of propagation whenever the GVD parameter β_2 and the chirp parameter C happen to have opposite signs such that $\beta_2 C$ is negative. The optical pulse then propagates undistorted in the form of an optical soliton.

The nonlinear Schrödinger (NLS) equation governing pulse propagation inside optical fibers can be written in the following form:

$$i \frac{\partial u}{\partial z} + \frac{1}{2} \frac{\partial^2 u}{\partial \tau^2} + |u|^2 u = 0, \quad (1)$$

where τ is a measure of time from the pulse center and is normalized to the input pulse width T_0 , and L_D is the dispersion length. Noting that $z = Z/L_D$, the soliton period Z_0 is defined as

$$Z_0 = \frac{\pi}{2} L_D = \frac{\pi}{2} \frac{T_0^2}{|\beta_2|}. \quad (2)$$

Figure 1. Soliton bit stream in the return-to-zero format where each soliton occupies a fraction of the bit slot representing 1 in a bit stream.

Temporal solitons are attractive for optical communications because they are able to maintain their width even in the presence of fiber dispersion, but their use requires substantial changes in the fiber system design, compared with conventional (nonsoliton) systems.

The basic idea is to use a soliton in each bit slot representing 1 in a bit stream. Figure 1 shows schematically a soliton bit stream in the return-to-zero (RZ) format. Typically, the spacing between two solitons exceeds a few times their full-width at half-maximum (FWHM), and individual solitons are well isolated. This requirement relates the soliton width T_0 to the bit rate B as $B = 1/T_B = 1/(2q_0T_0)$, where T_B is the duration of the bit slot and $2q_0 = T_B/T_0$ is the separation between neighboring solitons in normalized units.

The relatively large spacing necessary to avoid soliton interaction, limits the bit rate of soliton communication systems. The spacing can be reduced by up to a factor of two using unequal amplitudes for the neighboring solitons, so this scheme is feasible in practice and can be useful for increasing the system capacity.

Temporal solitons use the nonlinear phenomenon of SPM to maintain their width even in the presence of fiber dispersion. However, this property holds only if fiber losses are negligible. Optical amplifiers can be used for compensating fiber losses. Two approaches used for the management of losses through amplification of solitons are the lumped- and distributed-amplification techniques.

In the lumped-amplification scheme, optical amplifiers are placed periodically along the fiber link such that fiber losses between two amplifiers are exactly compensated by the amplifier gain. An important design parameter is the spacing L_A between amplifiers, which should be as large as possible to minimize the overall cost. For nonsoliton systems, L_A is typically 80–100 km. For soliton systems, L_A is restricted to smaller values because of the soliton nature of signal propagation.

The physical reason behind smaller values of L_A is that optical amplifiers boost soliton energy to the input level over a length of a few meters without allowing for gradual recovery of the fundamental soliton. The amplified soliton adjusts its width dynamically

in the fiber section following the amplifier, but it also sheds a part of its energy as dispersive waves during this adjustment phase. The dispersive part can accumulate to significant levels over a large number of amplification stages and must be avoided. One way to reduce the dispersive part is to reduce the amplifier spacing L_A such that the soliton is not perturbed much over this short length. Numerical simulations show (Hasegawa & Kodama, 1995) that this is the case when L_A is a small fraction of the dispersion length ($L_A \ll L_D$). The dispersion length L_D depends on both the pulse width T_0 and the GVD parameter β_2 and can vary from 10 to 1000 km, depending on their values.

The condition $L_A \ll L_D$, imposed on loss-managed solitons when lumped amplifiers are used, becomes increasingly difficult to satisfy in practice as bit rates exceed 10 GB/s. This condition can be relaxed considerably when distributed amplification is used. The distributed-amplification scheme is inherently superior to lumped amplification because its use provides a nearly lossless fiber by compensating losses locally at every point along the fiber link. In fact, this scheme was used as early as 1985 using the distributed gain provided by Raman amplification (Agrawal, 2002) when the fiber carrying the signal was pumped at a wavelength of about 1.46 μm using a color-center laser (Hasegawa & Kodama, 1995). Alternatively, the transmission fiber can be doped lightly with erbium ions and pumped periodically to provide distributed gain. Several experiments have demonstrated that solitons can be propagated in such active fibers over relatively long distances.

Early soliton experiments on loss compensation used the Raman-amplification scheme. The situation changed with the application of erbium-doped fiber amplifiers from around 1989 for loss-managed soliton systems. In a typical experiment (Agrawal, 2002), 2.5 GB/s solitons were transmitted over 12,000 km by using a 75 km fiber loop containing three amplifiers, spaced 25 km apart (Agrawal, 2002). The bit rate–distance product of $BL = 30$ (TB/s)km is limited mainly by the timing jitter induced by amplifiers.

Dispersion management, which consists of a periodic change of the dispersion β_2 along the fiber

length, is employed commonly for modern wavelength-division multiplexed systems. The use of dispersion management forces each soliton to propagate in the normal-dispersion regime of a fiber during each map period. If the map period is a fraction of the nonlinear length, the nonlinear effects are relatively small, and the pulse evolves in a linear fashion over one map period. On a longer length scale, solitons can still form if the nonlinear effects are balanced by the average dispersion. As a result, solitons can survive in an average sense, even though not only the peak power but also the width and shape of such solitons oscillate periodically.

Since 1996, a large number of experiments have shown the benefits of using dispersion-managed solitons for optical communication systems (Agrawal, 2002). Presently, 10 GB/s dispersion-managed solitons can be transmitted over 16 Mm of standard fiber when soliton interactions are minimized by choosing the location of amplifiers appropriately. An important application of dispersion management consists of upgrading the existing terrestrial networks designed with standard fibers and operating in the linear regime.

ORDER FROM CHAOS

At first glance, the words *chaos* and *order* seem to be contradictory. Indeed they are contradictory in terms of common definitions of the words, but not in terms of their mathematical usages. The definition of *chaos* in the Oxford American Dictionary (1986) is “great

disorder or confusion.” In contrast, the mathematical notion of *chaos* explains that data that seems to be random may have been generated by a deterministic and ordered process. In this sense, the field might have profitably been called “order theory” instead of “chaos theory.” There are two common usages of the phrase “order from chaos.” The first refers to seeking deterministic “chaotic” models to explain complex phenomenon, thus “order *in* chaos.” The second refers to the fact that some chaotic dynamical systems can also exhibit regular islands of simplicity within their phase space, or “order *from* chaos.” We will discuss each in turn.

Order in Chaos

The fact that seemingly simple and deterministic evolution rules can give rise to extremely complicated motion dates to Henri Poincaré (1892), in the setting of celestial mechanics. Perhaps the most famous example of unpredictable behavior is due to Edward Lorenz (1963), who discovered that even the most simplified models of the weather could produce data for which it is impossible to make long-term forecasts. Lorenz identified the “butterfly effect,” or “sensitive dependence to initial conditions,” whereby even small measurement errors quickly grow to swamp the signal. In 1975, Tien Yien Li and James A. Yorke published a paper entitled, “Period Three Implies Chaos,” (Li & Yorke, 1975). The most famous impact of this paper was that it coined the word *chaos*, the field of study describing the nonlinear effect in which even the simple systems of Poincaré, Lorenz, and others can display sensitive dependence in a bounded domain. The chaos theory has attracted a great deal of popular attention, partly, in fact, due to its sexy title. Part of the appeal is also due to the scientific tradition since the time of Newton of searching for mechanistic explanations of reality.

The concept of phase space is useful for mapping the behavior of a dynamical system. Phase space could be described as the set of all possible relevant variables, which creates a closed description of the time evolution of the system (*See* Phase space). For example, for a simple pendulum, we need to specify all possible angular position and angular momentum states to uniquely define all solutions; the phase space for the periodic oscillation is a closed curve, a circle. For an electronic tank oscillator (LRC) circuit, we need to specify capacitor charge and current through the inductor. The dimension of the system is the dimension of the phase space. A billiard table’s worth of balls, for example, requires many variables for a complete description—two variables for position and two for momentum for each of the balls.

As a highly interdisciplinary field, chaos theory has been successful in finding deterministic chaos, or order, in what was once thought to be mere noise, or at

Figure 1. This seemingly stochastic data was actually generated by a “simple,” low-dimensional, and deterministic process. This time-series plot of the state x_n versus time n was actually generated by the dynamical system $x_{n+1} = ax_n(1-x_n)$ called the logistic map. ($a = 4.0$, $x_0 = 0.44$).

least an extremely high-dimensional effect. There are numerous explicit examples of chaos in many areas, including biology, electrical engineering, chemistry, celestial mechanics, and brain and heart physiology. Thus, the old idea that extremely complicated data must always be due to extremely complicated effects is false (see Figure 1). One popular misuse of these ideas is a belief that all complicated data must have underlying order in chaos. This can be phrased as “Is what seems complicated always really simple?” The answer, of course, is no; it remains true that noise and other high-dimensional effects can also be responsible for complexity. What is true is that what seems complicated may *sometimes* be simple, in the sense of having a low-dimensional chaotic model. To cite one popular question, the stock market prices unarguably constitute extremely complicated data, but is there underlying order in chaos here, or is the explanation due to intractably high-dimensionality?

Order from Chaos

Some chaotic systems have an occasional tendency to exhibit simple behavior. This is often described as regular islands in an otherwise chaotic phase space. The classic mathematical example of regular islands arises in Hamiltonian systems, which can exhibit a phase space of solutions in which chaotic solutions are both intermingled and bounded by nested islands around islands around islands, and so on, of KAM-like tori (circle-like integrable solutions) (Arrowsmith & Place, 1990; Meiss, 1992).

Put differently, “order from chaos” and “regular islands” are terms commonly used to refer to the presence of an “attractor” (an imaginary point in the phase space about which the trajectories appear to orbit) in a system that one thinks should behave in a complicated manner. For example, consider a thought experiment of a game of pool in which we assume no friction so that the balls never stop moving (a two-dimensional Lorentz gas). Following the path of one specific ball, say the seven-ball, is an extremely

complicated problem displaying sensitive dependence, since a small change in the velocity or position of the ball affects the next collision with the wall or with the next ball, an effect that multiplies upon subsequent collisions. However, there are several attractors near which the ball’s motion becomes quite simple—the pocket holes. Once within the rim of a pocket (its basin of attraction), falling in becomes inevitable, as it would require a relatively large energy perturbation to prevent it from falling in. In this sense, we can say that the regions of phase space, corresponding to being stuck in the billiards pocket, are regular islands in a chaotic sea.

As analogies, such descriptions of islands in chaotic seas have been extended by some to explain the emergence of a coherent phenomenon from complicated processes. There is perhaps no more intriguing question than the origins of life. Proponents of emergence theories suggest that life in the original Hadean seas (the “primordial” seas on early Earth) gave rise to life through a capture process such as the billiards game (Waldrop, 1992; Kauffman, 1995). While randomly chosen initial conditions in the billiards game may each individually be unlikely to lead to capturing a ball in a pocket (and certainly any analogous attractors in chemical processes must be exceedingly unlikely), the way to win an unlikely bet is to play very quickly, over and over. This may have been the process that led to complex organic molecules, according to proponents of the emergence theory.

Emergence and order from chaos have also been used to describe processes whose attractors are surprisingly complicated themselves, as sets, but arise from surprisingly simple rules. Michael Barnsley has called the following “The Chaos Game” (Barnsley, 1993). First label the vertices of a triangle, 1, 2, 3. Using a random number generator (such as a six-sided die), assign probabilities to each triangle vertex, say die sides 1–2 to vertex 1, die sides 3–4 to vertex 2, and die sides 5–6 to vertex 3. Roll the die to randomly select one of the vertices, and record its planar coordinates (x, y) . Then roll the die again to randomly select another vertex, and record the point halfway between the resulting new vertex and the current (x, y) as the new (x, y) . Repeat indefinitely. For each newly defined (x, y) , we record a dot for a pictorial record. Most people guess that the result will uniformly fill the triangle with a smattering of dots, but the mathematical fact is surprising. The result is an extremely intricate structure, a fractal called the Sierpinski gasket (see Figure 2). Because this simple rule gives rise to such a complicated structure, the argument goes, perhaps many of the other intricacies we see around us might have emerged from other simple rules.

Finally, we mention the meaning of “order from chaos,” as developed from theories of the Nobel prize-winning physicist Ilya Prigogine, whose work on dissipative structures of systems held from thermal

Figure 2. From such a simple algorithm as “The Chaos Game” (Barnsley, 1993) emerges the extremely intricate fractal shown, called the Sierpinski gasket.

equilibrium has been used to study self-organizing systems (Prigogine, 1984). Prigogine has defined complexity as the ability to switch between different modes of behavior as the environmental conditions vary. Thus, he has described a phenomenon in which far-from-equilibrium systems transition “from being to becoming,” which some describe as order from chaos.

ORDER PARAMETERS

Although the concept of an order parameter was introduced by Lev Landau in the 1930s, it does not yet have a precise definition. Broadly, an order parameter is a thermodynamic quantity that is invariant with respect

Figure 1. A typical plot of the scalar order parameter as a function of temperature.

to the symmetry group of the low-temperature phase and zero above a critical point or transition temperature, T_c . It is a measure of the amount of order that is built up in the system in the neighborhood of the critical point. In general, an order parameter has both an amplitude and a phase. To find the equation of state, a minimization procedure is followed for an appropriate thermodynamic potential.

From the original application to second-order phase transitions where it changes continuously from T_c to lower temperatures, the idea of an order parameter has been extended to first-order transitions involving an abrupt change at T_c (see Figure 1). The concept of an order parameter has been generalized from a globally defined scalar to a complex time- and space-dependent function. Note that first-order phase transitions are associated with discontinuities of the order parameter and thermal hysteresis effects. Second-order phase transitions have a continuous order parameter and show field-induced hysteresis. Diverse applications of the order parameter concept to both equilibrium and non-equilibrium critical phenomena are listed in Table 1.

Crystal formation is demonstrated by the existence of a regular diffraction pattern associated with the Fourier components of the mass density distribution $\rho(\mathbf{r})$

$$\rho(\mathbf{r}) = \sum_{\mathbf{g}} \rho(\mathbf{g}) e^{i\mathbf{g} \cdot \mathbf{r}}, \quad (1)$$

where the $\mathbf{g}$ are vectors in the reciprocal space. The set of numbers $\rho(\mathbf{g})$ can be used as order parameters characterizing the low-temperature (crystal) phase. The nonzero coefficients $\rho(\mathbf{g})$ in Equation (1) define a multi-component order parameter.

The order parameter field for a magnet is defined at each position $\mathbf{x}$ by a direction of the local magnetization $\mathbf{M}(\mathbf{x})$ whose length is fixed. By becoming a magnet, this material has broken the rotational symmetry and its order parameter field defines the broken symmetry directions chosen in the material.

A number of metals, alloys, and ceramics below their critical temperature T_c exhibit an ordered state in the conduction electron degrees of freedom manifested by zero resistance. The order parameter for superconductors is the wavefunction of the Cooper pair

Phenomenon	Disordered phase	Ordered phase	Order parameter
<i>Equilibrium</i>

Table 1. Examples of order parameters (OPs).

condensate $\eta(\mathbf{r})$, and it exhibits a Hopf bifurcation at $T = T_c$.

The superfluid properties in ^4He and ^3He are manifested by the absence of viscosity. The ^4He atoms are bosons that below a transition temperature T_λ , undergo the so-called Bose condensation into a $k=0$ mode. The associated order parameter is the condensate's quantum wavefunction. Because ^3He atoms are fermions, below T_λ they form Cooper pairs.

Liquid crystals are anisotropic fluids composed of strongly elongated molecules. The nematic phase is characterized by the existence of a direction to which most of the molecules are parallel, so the order parameter is a second rank tensor describing correlations along that direction. Numerous other examples of critical phenomena, such as binary fluids, the metal-insulator transition, polymer transitions and spin- and charge-density waves, have their own order parameters.

Landau deduced that second-order phase transitions are associated with symmetry breaking and can be qualitatively described by an order parameter η . Assuming that the free energy F depends on V , T , and η , the equilibrium conditions are:

$$\left. \frac{\partial F(T, V, \eta)}{\partial \eta} \right|_{\eta=\eta_0} = 0$$

and

$$\left. \frac{\partial^2 F(T, V, \eta)}{\partial \eta^2} \right|_{\eta=\eta_0} > 0, \tag{2}$$

where η_0 is the equilibrium value of η .

The universality hypothesis states that any two physical systems with the same spatial dimensionality, d ,

Universality class	System	Order parameter (OP)
$d = 2, \quad n = 1$	Absorbed films	Surface density
$d = 2, \quad n = 2$	Superfluid ^4He film	Superfluid wave function
$d = 3, \quad n = 1$	Uniaxial ferromagnets	Magnetization
$d = 3, \quad n = 1$	Fluids	Density difference
$d = 3, \quad n = 1$	Mixtures, alloys	Concentration difference
$d = 3, \quad n = 2$	Planar ferromagnets	Magnetization
$d = 3, \quad n = 2$	Superfluids	Superfluid wave function
$d = 3, \quad n = 3$	Isotropic ferromagnets	Magnetization

Table 2. Examples of universality classes.

and the same number of order parameter components, n , belong to the same universality class having identical critical exponents (see Table 2).

Order parameters accompany broken symmetry phenomena where the new ground state of the system does not possess the full symmetry of the Hamiltonian. A classic example is the ferromagnetic-to-paramagnetic phase transition at T_c where the full rotational symmetry of the paramagnetic phase is broken by the axiality of the ground ferromagnetic state below T_c . When a symmetry that is broken is continuous, a vibrational mode appears whose frequency vanishes at long wavelengths. (Quanta of such modes are called "Goldstone bosons.") Examples include ferromagnetic domain walls and acoustic soft modes in structural phase transitions.

There exist several different types of broken symmetries: (a) translational (crystal formation, structural transitions); (b) gauge (superfluidity, superconductivity); (c) time reversal (ferromagnets); (d) local rotational (liquid crystals); (e) rotational (some structural phase transitions); and (f) space inversion (ferroelectricity). Gauge symmetry is a universal property of Hamiltonians whenever the total number of particles is conserved or a generalized charge-like conserved quantity exists. Then, the order parameter η is complex, and its local density $\rho = \eta^* \eta(r)$ is such that a phase shift $\eta \rightarrow \eta e^{i\omega}$ leaves the Hamiltonian invariant.

Defects in the order parameter space can be topological (i.e., kinks, also referred to as domain walls) and nontopological (i.e., solitons, also called nucleation centers). They are obtained as solutions to the equations of motion for the order parameter field. Also, point defects, line defects, vortices, dislocations, vacancies, and interstitials with attendant singularities are seen experimentally in critical systems (systems close to a phase transition).

Finally, note that Haken's separation of modes in synergetic systems into masters (order parameters) and slaves has been influenced by Landau's theory of phase transitions.

ORDINARY DIFFERENTIAL EQUATIONS, NONLINEAR

An ordinary differential equation (ODE) is an equation

$$\Delta(t, f, f', f'', \dots, f^{(N)}) = 0 \quad (1)$$

(with $f^{(j)} = d^j f / dt^j$), relating a function $f(t)$ to its derivatives. The order of an ODE is the size of the highest derivative that appears, so Equation (1) is N th order. An ODE is *linear* if it can be written as a linear

combination of f and its derivatives, that is,

$$\begin{aligned} \Delta \equiv & a_N(t) f^{(N)} + a_{N-1}(t) f^{(N-1)} + \dots \\ & + a_1(t) f' + a_0(t) f + b(t) = 0, \end{aligned} \quad (2)$$

including the possible addition of an inhomogeneous term $b(t)$. All other ODEs, which are not of the form (2), are referred to as *nonlinear*.

More generally, one can consider systems of ODEs relating M functions $f_0, f_1, \dots, f_{M-1}$ and their derivatives $f_k^{(j)}$ of different orders. In fact, if a system of ODEs can be solved for the highest derivatives appearing (which generally requires the implicit function theorem), then it can always be converted to a system of first-order equations,

$$\begin{aligned} f'_0 &= F_0(t, f_0, f_1, \dots, f_{M-1}), \\ f'_1 &= F_1(t, f_0, f_1, \dots, f_{M-1}), \\ &\vdots \\ f'_{M-1} &= F_{M-1}(t, f_0, f_1, \dots, f_{M-1}). \end{aligned} \quad (3)$$

For example, suppose Equation (1) can be solved explicitly for the N th derivative, as $f^{(N)} = F(t, f, f', f'', \dots, f^{(N-1)})$. In that case, the single ODE (1) may be rewritten as the first-order system

$$\begin{aligned} f'_0 &= f_1, \\ f'_1 &= f_2, \\ &\vdots \\ f'_{N-2} &= f_{N-1}, \\ f'_{N-1} &= F(t, f_0, f_1, f_2, \dots, f_{N-1}). \end{aligned}$$

In most applications of nonlinear ODEs, such as in the physical sciences or biology, they appear as coupled systems of either first or second order. For example, Newton's equations in mechanics (Arnol'd, 1989) are of the form

$$\mathbf{q}'' = \mathbf{F}(t, \mathbf{q}, \mathbf{q}'),$$

relating the acceleration $\mathbf{q}''$ of a particle (of unit mass) to the force $\mathbf{F}$ acting on it, which is a function of its position $\mathbf{q}$ and velocity $\mathbf{q}'$, and possibly the time t . Mechanical systems are often derived from an action functional $S = \int_0^1 L(t, \mathbf{q}, \mathbf{q}', \dots, \mathbf{q}^{(j)}) dt$. In particular, if $\mathbf{q}'$ is the highest derivative appearing in the Lagrangian, so that $L = L(t, \mathbf{q}, \mathbf{q}')$, then the corresponding Euler–Lagrange equations form a second-order system of ODEs, viz.

$$\frac{dL}{d\mathbf{q}} - \frac{d}{dt} \left(\frac{\partial L}{\partial \mathbf{q}'} \right) = 0.$$

In Hamiltonian mechanics, on the other hand, the equations of motion are given as a first-order system of ODEs,

$$\frac{d\mathbf{x}}{dt} = \mathbf{J}(\mathbf{x}) \nabla H(t, \mathbf{x}), \quad (4)$$

describing the evolution of a point x in the phase space with Poisson tensor J and Hamiltonian H . First-order equations are commonly used both in population dynamics, for example, the Verhulst model

$$\frac{dP}{dt} = rP(1 - P/K) \quad (5)$$

(with r, K constants), and in reaction kinetics applying the Law of Mass Action (Murray, 1989). The ODEs describing a system of N species or N chemical reagents typically take the form of N coupled first-order ODEs, but usually these are *not* Hamiltonian.

Given an ODE such as (1), the main task is to determine the nature of the solutions, namely, those functions $f(t)$ for which all the derivatives $f^{(j)}$ exist for $j=1, \dots, N$ and are related by Equation (1). More specifically, one may wish to solve an initial value problem, where the values $f(t_0), f'(t_0), \dots, f^{(N-1)}(t_0)$ of the function f and its first $N-1$ derivatives are specified at some initial time $t=t_0$, and f is to be determined at subsequent times $t > t_0$. Alternatively, one might pose a boundary value problem where the values $f(t_0)$ and $f(t_1)$ (and maybe some of the derivatives) are given at the endpoints of the interval $[t_0, t_1]$, and $f(t)$ is to be found for $t_0 < t < t_1$.

For an N th-order linear homogeneous ODE, of the form (2) with $b \equiv 0$, the general solution is just a linear combination of N -independent solutions s_j , that is, $f(t) = \sum_{j=1}^N A_j s_j(t)$ with N arbitrary constants $A_1, \dots, A_N$. Ideally, one would like to express the general solution of an N th-order nonlinear ODE as a function of N arbitrary integration constants, but in general this is not possible. However, for systems (3) where the F_j on the right-hand sides are suitably regular functions of all their arguments in the neighborhood of the initial data, the local existence of a solution to the initial value problem near $t=t_0$ can be proved by the Cauchy–Lipschitz method (Ince, 1926). In fact, whenever the F_j are analytic functions, then the existence of a local solution to the initial value problem is guaranteed in some circle around $t=t_0$ in the complex t plane (Hille, 1976). This means that, at least locally, the solution $f(t)$ can be considered as a function of the initial data $f(t_0), f'(t_0), \dots, f^{(N-1)}(t_0)$. Only for ODEs of Painlevé type can this local solution be extended globally to a single-valued, meromorphic function of t (Hinkkanen & Laine, 1999). In contrast, the solutions of other ODEs can display chaotic behavior, with coalescing branch points in the complex plane (Sachdev, 1991).

For first-order equations ($N=1$), there are various classes of ODEs that are amenable to exact integration methods. The simplest example is the class of *separable* equations, which are directly solvable by a quadrature:

$$\frac{df}{dt} = T(t)/F(f),$$

whence

$$\int F(f) df = \int T(t) dt + \text{constant}.$$

The Verhulst model (5) is a particularly simple example for we have

$$\begin{aligned} \int \frac{dP}{P(1 - P/K)} &= \log \left(\frac{P}{K - P} \right) = rt + c \\ \Rightarrow P(t) &= \frac{K}{1 + e^{-rt-c}} = \frac{KP_0}{P_0 + (K - P_0)e^{-rt}}, \end{aligned}$$

where the constant $P_0 = K/(1 + e^{-c}) = P(0)$ is the initial population size. Other special classes of first-order equations include the Bernoulli equations $f' = P(t)f + Q(t)f^n$ and Riccati equations $f' = A(t)f^2 + B(t)f + C(t)$; both of these types can be converted to linear equations by a substitution (Ince, 1926).

Among higher-order ODEs, exactly solvable equations are rare, but nevertheless some exact solution methods exist. In particular, if there are first integrals (constants of motion) or symmetries for a system, then it is possible to reduce the order. For autonomous Hamiltonian systems of order $N = 2n$, Liouville's theorem on integrable systems states that if there are n independent first integrals, in involution with respect to the nondegenerate Poisson bracket defined by J , then the ODEs (4) can be integrated by quadratures (Arnol'd, 1989). More generally, an ODE of order N with a first integral can be reduced to an equation of order $N-1$, while if it has a Hamiltonian or Lagrangian structure invariant under a symmetry of the system, then (using Noether's theorem) the order can be reduced to $N-2$. The approach to solving ODEs using their symmetries is originally due to Lie; for a modern treatment, see Olver (1993).

As an illustration of some of these ideas, consider the second-order ODE

$$f'' = \left(kt - \frac{(n-1)}{f} \right) (f')^2 + \frac{(n-1)}{t} f' \quad (6)$$

(k, n constants), which is a radial symmetry reduction of an n -dimensional partial differential equation appearing in differential geometry (Abreu, 1998). This can be derived from the action

$$\begin{aligned} S &= \int_{t_0}^{t_1} L(t, f, f') dt, \\ L &= t^{n-1} \log(f^{n-1} f') - kt^n f. \end{aligned} \quad (7)$$

By a Legendre transformation, setting $q = f$ and $p = \partial L / \partial f'$, (6) can also be converted to the first-order Hamiltonian form

$$\frac{d}{dt} \begin{pmatrix} q \\ p \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \begin{pmatrix} \partial_q H \\ \partial_p H \end{pmatrix}$$

with $H(t, q, p) = t^{n-1} \log(q^{n-1}/p) - kt^n q$. Because this is a non-autonomous system, with t appearing explicitly, the Hamiltonian H is *not* a constant of motion. However, (6) is invariant under the one-parameter group of scaling symmetries $r \rightarrow \mu r$, $f \rightarrow \mu^{-1} f$, so by introducing the new scale-invariant independent variable $y = ft$, and the dependent variables $v = v(y) = -\log t$, $w = dv/dy$, it reduces to a first-order equation for $w(y)$:

$$\frac{dw}{dy} = y(2n - ky)w^3 + (3n - 2ky)w^2 + ((n - 1)/y - k)w.$$

Unfortunately, it is not possible to reduce this to a quadrature, since the action (7) is *not* invariant under scaling, unless $k = 0$ when the general solution to (6) is $f(t) = (At^n + B)^{1/n}$ (with A, B arbitrary constants).

Other important methods for ODEs include the Painlevé analysis of movable singularities (Kruskal & Clarkson, 1992), and asymptotic expansions around regular or irregular fixed singular points (Wasow, 1965; Tovbis, 1994).

OVERTONES

When a tonal sound, such as a note played on a flute, a human vowel sound, or a bell, is analyzed in the frequency domain by applying a Fourier transform to the acoustic pressure waveform, the spectrum consists of a large number of sharp lines. The component of lowest frequency is termed the “fundamental”, and the others are “upper partials” or “overtones.” If the frequencies of the overtones are all exact integer multiples of the frequency of the fundamental, then they are termed “harmonics.” The partial with frequency $f_n = nf_1$, where f_1 is the frequency of the fundamental, is the n th harmonic, so that the fundamental is the first harmonic.

A one-dimensional simple harmonic oscillator, or linear oscillator, in which the restoring force is proportional to displacement y from the equilibrium position, obeys the equation

$$m \frac{d^2 y}{dt^2} = -ky, \quad (1)$$

where m is the mass of the moving particle and k is the restoring force constant. A damping term can also be included, but this need not concern us here. Such an oscillator vibrates with a single frequency $f_1 = (1/2\pi)(k/m)^{1/2}$ that is independent of oscillation amplitude. It is useful to think of this oscillator in terms of its potential energy function, which is quadratic as shown in Figure 1(a). In real oscillators, the restoring force is not linear for large displacements, but nonlinear so that

$$m \frac{d^2 y}{dt^2} = -ky(1 + \alpha_1 y + \alpha_2 y^2 + \cdots), \quad (2)$$

where the α_n are constants. The energy curve then has a distorted parabolic form such as that shown as an example in Figure 1(b). In the absence of damping, the total energy must remain constant so that the magnitude of the velocity is a simple function of the displacement, and the motion repeats cyclically. This means that the spectrum of such a nonlinear oscillator consists of exact phase-locked harmonics of the fundamental frequency, though this fundamental frequency depends upon the amplitude of the motion. For a reason that is derived from molecular physics, as discussed below, such a nonlinear oscillator is often confusingly called an “anharmonic oscillator.”

A thin taut string of length L ideally obeys an equation of the form

$$m \frac{\partial^2 y}{\partial t^2} = T \frac{\partial^2 y}{\partial x^2}, \quad (3)$$

where x measures length along the string, m is the mass per unit length, and T is the string tension.

Figure 1. (a) Potential energy curve for a simple harmonic oscillator. (b) Potential energy curve for a typical nonlinear oscillator such as a diatomic molecule.

If its ends are rigidly fixed, then the mode frequencies are exact harmonics of the fundamental so that $f_n = (n/2L)(T/m)^{1/2}$. It is thus a multimode harmonic oscillator. The nonlinear frictional action of the bow on a violin reinforces the harmonicity of the modes and locks them into rigid phase relationship (Fletcher, 1999). Something very similar happens with wind instruments, which also have precisely harmonic spectra.

A thin stiff bar, on the other hand, obeys an equation of the form

$$m \frac{\partial^2 y}{\partial t^2} = K \frac{\partial^4 y}{\partial x^4}, \quad (4)$$

where K is the elastic stiffness. If the ends are free or rigidly clamped, then the mode frequencies are approximately $f_n \approx \frac{4}{9}(n + \frac{1}{2})^2 f_1$, and the overtones are very far from being harmonically related. Such an oscillator might be termed “inharmonic.” The modes of a three-dimensional object such as a bell are even more complex (Fletcher & Rossing, 1998).

While sustained-tone musical instruments depend upon the nonlinearity of the active generator for their operation (bow, reed, or lip air-flow), the linear resonator (string or air column) determines the oscillation frequency, so that the pitch is nearly independent of loudness, and only the relative amplitudes of the harmonics change (Fletcher, 1999). Some Chinese opera gongs, however, make a virtue of nonlinearity so that, after an impulsive excitation, the pitch either rises or falls dramatically as the vibration dies away (Fletcher, 1985). The frequencies and relative intensities of upper partials determine the tone quality of a musical sound and have dictated the development of musical scales and harmonies (Sethares, 1998).

The human auditory system itself has some nonlinear aspects (Zwicker & Fastl, 1999), and, as in any forced nonlinear oscillator, these lead to the generation of harmonics (“harmonic distortion”) and of multiple sum and difference tones (“intermodulation distortion”). In the ear these are chiefly apparent in the generation of the difference tone $|f_1 - f_2|$ when loud tones of frequencies f_1 and f_2 are heard simultaneously.

Optical absorption and emission spectra have many similarities to acoustic phenomena (Herzberg, 1950; Harmony, 1989). Diatomic molecules, for example, have interatomic potentials of the form shown in Figure 1(b) and thus constitute nonlinear oscillators. If the interatomic potentials were simply parabolic, as in Figure 1(a), then the quantum energy levels would have the form $E_n = (n + \frac{1}{2})h\nu$, where h is Planck's constant and ν is the classical vibration frequency labeled f_1 above. The wave functions describing the atomic vibration would then be either symmetric or antisymmetric, and the selection rule would dictate that n could change only by ± 1 . There would thus be only a single absorption band consisting of the vibrational transition $0 \rightarrow 1$ surrounded by the allowed rotational transition lines.

For a more realistic model of the interatomic potential, as in Figure 1(b), the energy levels can be written as

$$E_n = (n + \frac{1}{2})h\nu[1 + \beta_1(n + \frac{1}{2}) + \beta_2(n + \frac{1}{2})^2 + \dots], \quad (5)$$

where β_n are usually called the “coefficients of anharmonicity” and β_1 is always negative in practice. The asymmetry of the potential also relaxes the selection rule so that in addition to the strong allowed absorption transition $0 \rightarrow 1$, there are much weaker transitions from $n=0$ to higher levels. The absorption bands associated with these transitions have frequencies that are in approximate, but not exact, harmonic relationship to the fundamental, and are called “overtone bands.”

Although the quantum treatment of a nonlinear oscillator may seem to conflict with the classical treatment, and the term *anharmonic* certainly suggests this, there is not really any disagreement. The infrared spectrum is derived from transitions between two levels of different energies, and therefore different classical amplitudes, and the classical frequency depends upon amplitude, as for the Chinese opera gong.

P

PAINLEVÉ ANALYSIS

Most problems of physics, chemistry, biology, engineering, and practically every applied science are nonlinear, in the sense that effects are not related to their causes by simple proportionality. Further, in most cases, these problems are described by differential equations, which provide the rules by which the main observables (such as displacements, velocities, fields, chemical concentrations, or populations) vary with respect to changes in the continuous independent variables (space and/or time). If the independent variables are discrete, the governing rules become difference equations.

Unfortunately, there is no general theory for integrating differential equations globally, that is, for finding their solutions analytically, over the full domain of the independent variables and for arbitrary initial and boundary data. That is why scientists often concentrate their analysis in regimes where the system behaves linearly, for example, small vibrations of lattices and solid structures, Fourier's law of heat conduction, Ohm's and Kirchhoff's laws in electrical circuits, and Laplace's and Maxwell's equations in electromagnetism.

However, even in such problems, the theory of linear differential equations often meets with serious difficulties, when the solutions possess singularities, that is, space and/or time values at which these solutions or their derivatives become infinite. In linear problems, these singularities appear explicitly in the equations, and if they are of special form, the general solution can still be found analytically near the singularity, for example, in terms of convergent series expansions. The theory of Lazarus Fuchs and Ferdinand Frobenius was especially developed for this purpose in the 1860s and led to the remarkable discovery of special functions, associated with such classic second-order ordinary differential equations (ODEs), as those of Bessel, Hermite, Legendre, or the hypergeometric equation.

By contrast, nonlinear ODEs possess singular points that are not evident by inspection of the equation itself. For example, the famous Riccati equation

$$dx/dt = a + bx + x^2 \quad (1)$$

(a, b constant parameters) known since the 1700s (See **Riccati equations**), has solutions which behave as

$$x(t) = \frac{1}{t-c} + a_0 + a_1(t-c) + a_2(t-c)^2 + \dots, \quad (2)$$

where c is an arbitrary constant. Thus, this type of singularity, at $t=c$, is called movable, since its location depends on the choice of initial conditions. Furthermore, after the pioneering work of Augustin Cauchy in the 1830s showed the importance of complex variables, a new branch of mathematics developed in which ODEs are studied in the complex domain, with the independent variable taking values $t = t_R + it_I$, where $t_R, t_I \in \mathbb{R}$ are, respectively, the real and imaginary parts of t and $i = \sqrt{-1}$. As is well known, in this t -plane, the singularity at $t=c$ in (2) is called a pole and limits the convergence region of the Taylor expansion of the function $x(t)$ about any nearby point $t=t_0$ (where $x(t)$ is analytic), to $|t-t_0| < |c-t_0|$.

Still, when moving around a circle centered at the pole $t=c$ (and enclosing only this singularity), $x(t)$ always returns to the same values, implying that it is a single-valued function in that region. This is not what happens if $t=c$ is a branch point of $x(t)$ of the type

$$x(t) = (t-c)^\alpha + \dots \quad \text{as } t \rightarrow c \quad (3)$$

with α not an integer. For example, if α is a rational number, $\alpha = p/q$, it takes q turns around $t=c$ for $x(t)$ to return to its starting value, demonstrating that it is a multi-valued function, describing a finitely sheeted Riemann surface, while $t=c$ is called an algebraic singularity. If, on the other hand, α in (3) is irrational or complex, $t=c$ is called a transcendental branch point and $x(t)$ describes an infinitely sheeted Riemann surface. Finally, if an expansion of $x(t)$ about $t=c$ contains logarithmic terms of the form $\log(t-c)$, it is again an infinitely multi-valued function and $t=c$ is called a logarithmic branch point.

Paul Painlevé, the great French mathematician and statesman (he was Prime Minister of France in 1917 and 1925), pursuing the idea that the problems with the

simplest singularities would be the easiest to solve, set out to determine which first-order ODEs of the form

$$dx/dt = f(t, x) \quad (4)$$

with f rational in x and analytic in t , are free from movable branch points; that is, their only movable singularities are poles. His remarkable discovery was that there is only one such equation: the Riccati equation (1), with the coefficients of 1 , x , and x^2 being arbitrary analytic functions of t . Then, in a remarkable series of papers in the late 1890s and early 1900s, Painlevé and his coworkers (notably Bertrand Gambier) studied the same question on all second-order ODEs

$$d^2x/dt^2 = f(t, x, dx/dt) \quad (5)$$

with f rational in dx/dt , algebraic in x , and analytic in t . After painstaking analysis, they showed that there are 50 such equations, 44 of which can be explicitly integrated and solved in terms of known functions. For the remaining six equations (called Painlevé I–VI), such reduction was not possible, and new functions had to be introduced called the Painlevé transcendents. The first two of these equations are

$$\text{Painlevé I: } d^2x/dt^2 = 6x^2 + t,$$

$$\text{Painlevé II: } d^2x/dt^2 = 2x^3 + tx + a \quad (6)$$

with Painlevé III–VI being increasingly more complicated to write down. The interested reader will find them all discussed in the excellent books by Ince (1956) and Davis (1962), where Painlevé's approach to their discovery is also described.

It is important to recall, however, that independent of all this progress, the idea of using singularity analysis to solve systems of ODEs by requiring that their solutions have only poles was also used by the Russian mathematician Sophia Kovalevsky in 1888 to find one more solvable case of the rotating rigid body that bears her name (Kovalevsky's top). Still, the requirement that all solutions of a system of ODEs possess only poles as movable singularities in the complex t -plane has come to be referred to date as the Painlevé property.

Surprisingly enough, the Painlevé theory was not widely appreciated at first and remained largely unknown until it was revived, many decades later, in connection with exactly solvable partial differential equations (PDEs). More specifically, after the discovery that a number of PDEs are integrable by the inverse scattering transform (IST), Ablowitz and Segur observed in the mid-1970s that all ODE reductions of these PDEs had the Painlevé property and led, in fact, to some of the Painlevé I–VI equations, (6) (see Ablowitz & Segur, 1981, as well as Ablowitz & Clarkson, 1991).

Thus, the famous Ablowitz, Ramani, and Segur conjecture was formulated as follows: If a PDE is solvable by IST, all its ODE reductions obey the Painlevé property. Clearly, this conjecture provides

a useful criterion to test the integrability of a given PDE by studying its ODE reductions—a much easier task than showing whether or not it is solvable by IST.

This discovery had enormous consequences, as it attracted the attention of many researchers working in the rapidly expanding field of nonlinear dynamics. The fact that most nonlinear dynamical systems of ODEs possess “irregular,” “unpredictable,” or chaotic solutions evidently suggests that they cannot be integrated and solved in terms of known functions, whose behavior is perfectly regular and predictable. It would thus be extremely interesting to find, in models of physical, chemical, or biological dynamics, integrable cases whose solutions would be clearly distinguished from those displaying chaotic behavior.

Such new, integrable systems could now be identified by means of the Painlevé property. Perhaps one of the most important applications occurred in Hamiltonian systems, like the famous Hénon–Heiles problem

$$H = \frac{1}{2}(\dot{x}^2 + \dot{y}^2 + Ax^2 + By^2) + x^2y + \frac{C}{3}y^3 \quad (7)$$

of two degrees of freedom (dots denote differentiation with respect to t). For $A = B = 1$ and $C = -1$, this problem had been extensively studied since the mid-1960s, as an example of a system whose chaotic regions grow dramatically as the total energy $H = E$ increases from 0 to $\frac{1}{2}$. Using the Painlevé analysis, it was first shown by Bountis et al. (1982) that (7) is completely integrable in exactly three cases:

- (i) $C = 1$ and $A = B$ (known to be separable in the variables $s = x + y$, $d = x - y$).
- (ii) $C = 6$ and any A and B .
- (iii) $C = 16$ and $B = 16A$.

In each of the new cases (2) and (3), the second integral—besides Hamiltonian (7)—was also provided and their complete integrability in the sense of Liouville–Arnol'd was established.

Soon, many novel and highly nontrivial examples of Hamiltonian systems with N degrees of freedom were identified by requiring that their solutions possess the Painlevé property. Rigorous connections between integrability and the Painlevé property were also developed, mainly by Adler and van Moerbeke in the early 1980s, who used algebraic geometry to establish that if a Liouville–Arnol'd integrable Hamiltonian system has rational integrals which continue to describe tori in the complex domain, then its solutions have only movable poles (the converse, though not completely proved, is also believed to hold). A wealth of examples of integrable non-Hamiltonian systems were also discovered, related to models of physical, chemical, or biological interest. Finally, the Painlevé analysis was

extended and applied by Weiss, Tabor, and Carnevale to test integrability directly on a PDE, without reference to its ODE reductions (see Ramani et al., 1989).

But the importance of Painlevé analysis does not end here. After the early observation that any deviation from the Painlevé conditions generically introduces logarithmic terms, researchers began to look for connections between the violation of the Painlevé property and non-integrability, in the sense of non-existence of analytic, single-valued integrals such as (7). In that regard, the work of the Russian mathematicians V.V. Kozlov and S.L. Ziglin in the late 1970s turned out to be extremely important (see Kozlov, 1983). They showed, using Mel'nikov's theory, that one of the most fundamental causes of chaotic behavior, that is, the transverse intersection of stable and unstable manifolds of saddle fixed points on a Poincaré map, implies the presence of infinitely multi-valued solutions and non-existence of a second integral in a two-degree-of-freedom Hamiltonian systems.

Kozlov's and Ziglin's results inspired a series of interesting papers by H. Yoshida in the 1980s, where he used them to study the variational equations of simple periodic solutions in a large class of N -degree-of-freedom Hamiltonians. Yoshida was able to prove that when these variational equations do not satisfy certain conditions imposed by the existence of a full set of global single-valued integrals, such a set of constants cannot exist, thus demonstrating non-integrability for vast parameter ranges in many Hamiltonians of physical interest (see Ramani et al., 1989).

Finally, what about systems of ODEs (or PDEs) whose solutions possess only algebraic singularities, that is, points $t=c$, near which solutions have asymptotic expansions of the form

$$x(t) = (t-c)^{p/q} + \sum_{n=0}^{\infty} a_n(t-c)^{n/q} \quad (8)$$

without any other singularities present? In the 1980s, it was thought that this so-called weak Painlevé property, under some conditions on p/q , could also be related to complete integrability, in the Liouville–Arnol'd sense for N -degree-of-freedom Hamiltonian systems. In the 1990s, however, it was found that the situation is considerably more subtle.

First, it was shown by Goriely that many weak Painlevé examples could be transformed to systems having the usual Painlevé property after some rather general changes of coordinates (see Goriely, 2001). Then it was observed that there were weak Painlevé systems with chaotic solutions, which are evidently not integrable. Thus, the concept of globally finitely sheeted solutions (FSS) was introduced to distinguish integrable systems with algebraic singularities (8) from non-integrable ones, whose solutions are only locally finitely sheeted (see Bountis, 1992, 1995).

This is done as follows: every time a system of weak Painlevé ODEs, integrated numerically around arbitrarily large contours, showed evidence of “lattice” singularity patterns in the complex t -plane and FSS, it has been shown to be transformable to one that is completely integrable and possesses the usual Painlevé property. On the other hand, many such systems were also found which showed “dense” singularity patterns and evidence of globally infinitely sheeted solutions (ISS) for large enough contours. Although not solvable, such systems can still be integrable if they are hyperelliptically separable, that is, if they can be described by N holomorphic differentials on the Jacobian of a hyperelliptic curve of genus $g < N$ (see Abenda & Fedorov, 2000; Abenda et al., 2001).

Finally, in the 1990s, the connection between singularities and integrability was extended to discrete dynamical systems, described by difference equations. Here, since the methods of complex analysis for ODEs no longer apply, a novel criterion was introduced (see Grammaticos et al., 1991). It was based on the observation that if a difference equation such as

$$x_{n+1} = F(x_n, x_{n-1}), \quad n = 0, 1, 2, \dots \quad (9)$$

with F rational, possesses an integral of the form

$$I(x_n, x_{n-1}) = \text{const.}, \quad n = 0, 1, 2, \dots \quad (10)$$

yielding a family of curves in the x_n, x_{n+1} plane and precluding the presence of chaos, then x_n is infinite at some $n=m$ and becomes finite again at some later $n=m' > m$. This so-called singularity confinement criterion, whose success to date remains a mystery, has yielded a wealth of integrable discrete systems and has enabled many researchers to develop Painlevé difference equations, analogous to the famous Painlevé ODEs Painlevé I–VI (see Conte, 1999).

PARAMETRIC AMPLIFICATION

Parametric generation and amplification of oscillations are based on the phenomenon of parametric resonance, using the work done by an external force under periodic variation of the parameters of an oscillatory system.

A simple mechanical system in which parametric resonance may occur is a pendulum, with the length of the cord (l) changing with time. If l is decreased when the pendulum is in the lower position and increased in its upper position, the average work done by an external force over one period is positive and oscillations of the pendulum build up. This phenomenon is the underlying principle of setting a swing into motion. When one stands on a swing, it is easier to rock it by squatting at the top position of the swing and standing up at the bottom position, thus shifting the center of mass of the person on the swing twice in one period.

An electric analog of a pendulum of variable length is an oscillatory circuit of variable capacitance. The capacitance C can be changed, for example, by mechanically moving the capacitor plates together or apart. For the amplitude of oscillations to build up, energy should be fed to the circuit by performing work against the electrostatic field forces of the capacitor. This means that the plates should be moved apart when the charge q on the capacitor is maximal and moved together when the charge on the capacitor returns to zero (Figure 1).

Such a periodic change in capacitance (pumping-up process) results in growing energy of the oscillations and appearance of instability in the system. The build-up of energy occurs at a pump frequency satisfying the relation

$$\omega_p = 2\omega_0/n, \quad (1)$$

Figure 1. Periodic variations of capacitance C of capacitor (a), capacitor charge q (b), and voltage u (c) at parametric resonance.

Figure 2. Mathieu instability zones within which parametric resonance may occur (solid line—without damping; dashed line—with damping; ω_0 natural frequency of the oscillatory circuit; ω_p pump frequency).

where n is an integer, ω_0 is the natural frequency of circuit oscillations, and ω_p is the pump frequency. Build-up is most effective for $n = 1$, that is, when the period of capacitance variation is half the period of natural oscillations of the circuit. Interestingly, energy build-up (parametric resonance) is possible not only for the values of ω_p satisfying Equation (1) but also at some deviations from these values within Mathieu instability zones (see Figure 2). The greater the width of Mathieu zones, the greater the extent of parameter variation $m = (C_{\max} - C_{\min}) / (C_{\max} + C_{\min})$.

In oscillatory systems with several degrees of freedom (e.g., in a system with two coupled circuits, coupled pendulums, and so on), normal modes with different natural frequencies ω_1 and ω_2 may exist. As parameters of such a system change, oscillations may build up (parametric resonance) not only at a frequency satisfying condition (1) for an arbitrary natural frequency, but also for their linear combination, for instance, when a parameter changes with sum

frequency

$$\omega_p = \omega_1 + \omega_2. \quad (2)$$

Resonance coupling is also possible at $\omega_p = \omega_1 - \omega_2$. In this case, however, no build-up of oscillations occurs. Instead, energy is periodically pumped between the modes ω_1 and ω_2 . For such an oscillatory system, the pump power P_p input to the system at frequency ω_p and the powers P_1 and P_2 consumed at frequencies ω_1 and ω_2 are proportional to the corresponding frequencies (the Manley–Rowe relation):

$$\frac{P_p}{\omega_p} = \frac{P_1}{\omega_1} = \frac{P_2}{\omega_2}. \quad (3)$$

Parametric resonance may also provide conditions for excitation of normal modes in oscillatory media possessing an infinite number of degrees of freedom. In 1831, Michael Faraday had observed that standing waves are excited at frequency $\omega_p/2$ in the liquid in a vessel vibrating in the vertical direction at frequency ω_p . The classic experiment staged by Franz Melde in 1859 revealed excitation of transverse oscillations (standing waves) in a string, one end of which was fastened to the prong of a tuning fork. When the tuning fork vibrates and the string is tight, the string performs transverse oscillations with a frequency equal to half the frequency of the tuning fork.

A distinguishing feature of parametric resonance in systems with distributed parameters is that the build up of oscillations depends strongly on the relationship between the variation in space of the system parameters and the spatial structure of the forcing oscillations (waves). For example, if the pump that changes the parameters of the medium is a traveling wave with frequency ω_p and wave vector $\mathbf{k}_p$, then natural waves with frequencies ω_1 and ω_2 and wave vectors $\mathbf{k}_1$ and $\mathbf{k}_2$ are excited, provided the conditions of parametric resonance are fulfilled both in space and time; thus

$$\omega_p = \omega_1 + \omega_2, \quad \mathbf{k}_p = \mathbf{k}_1 + \mathbf{k}_2. \quad (4)$$

The potentialities of using parametric resonance for creating a parametric generator and amplifier were studied by Leonid I. Mandelshtam and Nikolai D. Papaleksi (1931–1933). They constructed capacitive and inductive parametric machines that transformed mechanical energy into electrical energy as a result of variation of the magnitudes of capacitance and inductance during shaft rotation. Parametric generators and amplifiers found practical application in the 1950s when semiconductor parametric diodes appeared, the capacitance of which depends on applied voltage, and when variable capacitors using the properties of ferroelectrics and variable inductors using the properties of ferrites and superconductors were developed. Low-noise variable capacitance parametric amplifiers based on high-frequency parametric diodes (varactors) are used in high-frequency receiving

microwave devices employed in radar and radio astronomy, among other applications. Parametric generators are capable of generating oscillations whose phase can take one of two values differing by π . This feature of parametric generators was noted by Eiichi Goto who proposed in 1954 to use such generators, which he referred to as “parametrons,” as logic switching elements in computers. Parametric generators are widely employed in optics as tunable coherent generators.

Note finally that parametric action on a nonlinear oscillatory system (for example, a nonlinear pendulum with variable-length cord or a nonlinear circuit with periodically varying capacitance and inductance) may also lead to dynamic oscillations.

PARTIAL DIFFERENTIAL EQUATIONS, NONLINEAR

A partial differential equation (PDE) is a functional equation of the form

$$F\left(x_1, x_2, \dots, x_n, z_1, \dots, z_m, \frac{\partial z_\mu}{\partial x_\nu}, \dots, \frac{\partial^2 z_\mu}{\partial x_1^2}, \dots, \frac{\partial^2 z_\mu}{\partial x_1 \partial x_2}, \dots\right) = 0 \quad (1)$$

with m unknown functions $z_1, z_2, \dots, z_m$ with n independent variables $x_1, x_2, \dots, x_n$ ($n > 1$) and at least one of the partial derivatives of z_μ ($\mu = 1, 2, \dots, m$) with respect to x_ν ($\nu = 1, 2, \dots, n$). In general, there can be a system of coupled PDEs.

For a single equation, the order of the PDE is p if the highest derivative has order p , with an analogous definition for a system of equations. A PDE becomes an ordinary differential equation if the number of independent variables n is one. It is linear if the equation is linear with respect to z and its partial derivatives, meaning it is of the first degree in the unknown function as well as its derivatives. It is called quasilinear if

it is linear with respect to the highest-order partial derivatives which have coefficients that depend only on lower-order partial derivatives and the independent variables. In addition, a PDE is called semilinear if the coefficients of the highest-order derivatives depend on the independent variables only. A PDE is called nonlinear if it does not fit into any of the above categories.

Initial value problems (IVPs) for evolution equations arise where one of the independent variables x_i of Equation (1) represents time t and an initial condition at time $t = 0$ is given. Additionally, there are boundary value problems (BVPs), when spatial variables are involved and boundary conditions are specified along the n -dimensional boundary of the domain (where n is the number of independent spatial variables). There can also be mixed initial value-boundary value problems (IVBVPs), where both types of conditions are given.

For a single PDE, the number of initial conditions is generally one less than the highest temporal derivative, while the number of spatial boundary conditions is half the order of the highest spatial derivatives in the equation. For general nonlinear equations, there are no precise definitions.

Second-order semilinear PDEs have the general form

$$a \frac{\partial^2 z}{\partial x_1^2} + 2b \frac{\partial z}{\partial x_1 \partial x_2} + c \frac{\partial^2 z}{\partial x_2^2} + \text{l.o.t.} = 0,$$

where a, b, c are given functions of x_1 and x_2 or constants and l.o.t. stands for lower order terms. The coefficient matrix A of the corresponding second-order system has the determinant

$$\det A = \begin{vmatrix} a & b \\ b & c \end{vmatrix}. \quad (2)$$

A second-order semilinear PDE is said to be of elliptic type if $\det A (=ac - b^2) > 0$, of hyperbolic type if $\det A < 0$, and of parabolic type if $\det A = 0$ for all points x_1, x_2 of the domain D . The determinant of A is positive if both eigenvalues of the matrix A are positive or both negative. The determinant is negative if the eigenvalues are of opposite sign and zero if one of them is zero. The normal forms of the associated differential operators L are given by

$$\det A > 0: \quad \frac{\partial^2}{\partial x_1^2} + \frac{\partial^2}{\partial x_2^2} \quad (\text{elliptic}),$$

$$\det A < 0: \quad \frac{\partial^2}{\partial x_1^2} - \frac{\partial^2}{\partial x_2^2} \quad (\text{hyperbolic}),$$

and

$$\det A = 0: \quad \frac{\partial^2}{\partial x_1^2} \quad (\text{parabolic}).$$

Boundary value conditions may be "Dirichlet" (where the value of the solution is given along the

boundary ∂D of the domain D), "Neumann" (where the normal derivative $\partial z / \partial n$ is specified along the boundary ∂D), and "Robin" (where both the value and the normal derivative of the solution $\partial z / \partial n + az$ satisfy an equation along the boundary of the domain ∂D).

The archetypical example for an elliptic PDE is the Laplace equation

$$\frac{\partial^2 z}{\partial x^2} + \frac{\partial^2 z}{\partial y^2} = 0;$$

for a hyperbolic PDE, it is the wave equation

$$\frac{\partial^2 z}{\partial t^2} - c^2 \frac{\partial^2 z}{\partial x^2} = 0;$$

and for a parabolic PDE, it is the diffusion equation

$$\frac{\partial z}{\partial t} - \nu \frac{\partial^2 z}{\partial x^2} = 0.$$

The coefficient matrix A (2) can depend on first-order derivatives if the PDE is second-order quasilinear and the classes are analogous. Quasilinear and strictly linear second-order PDEs are classified according to these three classes. For a given nonlinear PDE of higher order or more than two variables, it is not useful to classify according to these three classes, instead, one classifies it according to the physical process it describes. In general, boundary value problems are often associated with elliptic equations and initial value problems with hyperbolic and parabolic equations.

Nonlinear PDEs describe many important processes in nature because often an approximate linear PDE is not sufficient to describe the process. Examples are the dynamics of fluids, gases, and elastic media; the equations from general relativity and quantum electrodynamics; and population dynamics in biology and chemistry.

The two main characteristics of such processes are the nonlinear interactions, due to the nonlinearities of the PDE and the possibility of self-organization into coherent structures.

There are three types of processes that one can distinguish. Reversible processes such as waves; irreversible; processes such as reaction, diffusion and heat flow; and stationary processes. A process is irreversible/reversible if it is impossible/possible to reverse the process in time and stationary processes are independent of time. In general, reversible processes are described by hyperbolic equations, irreversible processes by parabolic equations, and stationary processes by elliptic equations.

Most physical systems comprise a combination of all three types of processes, but often, some processes are dominant and by using a scaling argument, it is possible to neglect less dominant processes and

simplify the PDE to the degree that it describes the process adequately but is still easy to work with.

The nature of irreversible processes such as diffusion, is that they tend to smooth the solution in time, whereas for reversible processes singularities can develop, for example, shock waves in gas dynamics. For stationary processes, the solutions depend on the smoothness of the boundary conditions and external forces.

Solutions to nonlinear PDEs are often obtainable only by numerical integration. In integrable cases, on the other hand, analytic solutions can be found using advanced techniques such as the inverse scattering method, the associated Lax theory, and the Bäcklund transformation. There are other techniques that are helpful although not exact, such as Floquet and Mel'nikov theory.

In general, for nonlinear PDEs common tools such as the linear superposition principle are not valid anymore, although it is sometimes possible to find a nonlinear superposition principle. Methods such as the Fourier and Laplace transforms and Green's function, in general, are not applicable to nonlinear PDEs. Alternatively, one can attempt classical solution methods such as the separation of variables or transformation of variables to reduce the nonlinear PDE to a system of equations that is solvable analytically.

PARTICLE ACCELERATORS

Particle accelerators have been used for much of the 20th century to investigate the properties of matter. The first accelerators of charged particles used steady (d.c.) electric fields, such as those obtained from a Van de Graaff generator. These devices could accelerate particles to above an energy of a million electron volts (MeV), which was sufficient to probe atomic nuclei. Applications needing higher energies continually emerged, leading to new types of devices, particularly ones having the charged particles move in a circular orbit. In that configuration, with the additional concept that electric fields and particles

can be synchronized, such that on each crossing of a gap, particles encounter a field that is accelerating, the basic accelerator configuration was created. Such devices went through a series of developments from a fixed frequency cyclotron to a frequency modulated cyclotron and finally the synchrotron. In the first two devices, the equilibrium orbit spirals out as the energy increases, while in the last device, the orbit is held fixed, and the bending magnetic field is increased.

To keep the particles on a prescribed essentially circular orbit over many traversals of the device, the orbit must be stable to transverse perturbations. Furthermore, to achieve continuous acceleration, the particle motion must be stable about the equilibrium accelerating phase of the electric field. Because the particles are kept close to an equilibrium orbit, the transverse stability can be analyzed from linear stability analysis, using a first-order expansion of the fields about the equilibrium. When the gradients of the magnetic guide field are chosen to give stable oscillations around the equilibrium orbit, they are called betatron oscillations, after the betatron, an early circular induction accelerator for which the oscillations were first analyzed (Kerst & Serber, 1941). For particles traveling in a straight line, the forces resulting from magnetic gradients cannot focus in both transverse directions simultaneously. This is not true for circular orbits, as the gradient in the centrifugal force supplies an extra focusing force to allow focusing in both directions. The resulting homogenous linear equations of motion for the simplest, assumed azimuthally symmetric, device are

$$\frac{d^2 z}{d\theta^2} + nz = 0 \quad (1)$$

and

$$\frac{d^2 x}{d\theta^2} + (1 - n)x = 0, \quad (2)$$

where z is the vertical position and x the horizontal deviation from the equilibrium orbit r_0 , and θ is the azimuthal angle around the machine. Here, n is the field index

$$n = -\frac{r_0}{B_0} \frac{\partial B_z}{\partial r} \quad (3)$$

with B_0 the equilibrium magnetic field. From (1) and (2) the stability condition is $0 < n < 1$. The azimuthally symmetric focusing of this type is now called weak focusing because the limitations on stability make the relative frequencies or tunes $\nu_z \equiv \omega_z / \omega_0 = n^{1/2}$ and $\nu_x \equiv \omega_x / \omega_0 = (1 - n)^{1/2}$ both less than 1. The weak restoring forces required large vacuum chambers, limiting the size and field strength of the devices and therefore the energy to which particles could be accelerated.

The breakthrough in developing a synchrotron in which particles could be closely contained around their

equilibrium orbit was the understanding that much stronger focusing could be achieved by alternating a section which strongly focused vertically while defocusing radially with a section that defocused vertically and focused radially. The net result, from simple lens theory, is that the pair can be strongly focusing. This led to the invention of the alternate gradient (AG) synchrotron (Courant et al., 1952). The simplest analysis of the linearized equations of motion is of the Hill equation

$$\frac{d^2y}{d\theta^2} + K(\theta)y = 0 \quad (4)$$

with $K(\theta + \theta_L) = K(\theta)$, where θ_L is the repeating angular period. The transformation for a period can be analyzed for stability from Floquet theory by setting

$$y(\theta + \theta_L) = y(\theta)e^{\pm i\pi} \quad (5)$$

and solving the transfer matrix, over the repeating period θ_L , for stability. This was done in the original paper, for a simple transfer matrix, leading to a stability diagram. However, even the early AG synchrotrons were more complicated, with bending magnets, focusing quadruple magnets, and straight sections in which resonators supplied the acceleration fields. For various reasons, described in part below, modern machines with very large radii, operating at many billions of electron volts (BeV or GeV), are much more complicated, leading to stability calculations with a very large number of elements.

However, even at the simplest level, calculating the linear stability of orbits is not sufficient. Nonlinear terms, although small, can have very important consequences. The motions given by (1) and (2), or more generally by (4), in each of the transverse directions are independent. The nonlinear terms couple the transverse dimensions and lead to a wide variety of resonances that can degrade the beam cross section. These difference resonances of various strengths must be avoided when finding a proper operating point in the $v_x - v_z$ parameter space. Additionally, magnet imperfections lead to entirely new classes of resonances. The effect of the increasing energy, coupled with the space charge of the beam of ions or electrons, leads to a movement of the operating point through the parameter space, such that all resonances cannot be avoided.

In addition to the primarily linear transverse oscillations, there are fundamentally nonlinear oscillations associated with the accelerating fields, called synchronous oscillations. For circular devices, these oscillations couple longitudinal and transverse motions. The frequencies of these electric-field-driven oscillations are generally much lower than the transverse betatron oscillations so that it is usually sufficient to consider their radial motion as adiabatic when studying the free oscillations, that is, using averaging methods. Depending on how relativistic the particles are,

the phase motion may be either primarily longitudinal or radial. To simplify the treatment, we consider the synchronous motion in a linear accelerator such that transverse motions are unimportant to lowest order. The fields in both linear accelerators and synchrotrons are generated by high-power electromagnetic sources which operate in structures, for example, loaded waveguides in linear accelerators and resonant cavities in synchrotrons, that have a primary traveling-wave field synchronous with the particles. Nonsynchronous harmonic fields also exist, but are usually not important.

The equations of motion along the axis of a linear accelerator are the force equation

$$\frac{dp}{dt} = eE \sin \phi \quad (6)$$

and the equation for the change in phase

$$\frac{d\phi}{dt} = \omega \left(1 - \frac{v}{v_0}\right), \quad (7)$$

where v_0 is the wave velocity, ω the r.f. frequency, and E the applied field. The phase stable particle has $v = v_0$, and for stable acceleration, v_0 must be determined from (6), where p and v are relativistically related. The motion of particles around the stable phase is given by trajectories in the $p - \phi$ phase plane with the stable fixed point at $\phi = \phi_s$, satisfying $d\phi/dt = 0$, and an unstable fixed point on a separatrix orbit satisfying, $\phi_u = -\phi_s$. The phase diagram indicates that particles injected between ϕ_u and some limiting ϕ on the separatrix trajectory with velocity v_0 oscillate nonlinearly about ϕ_s , while those outside the phase interval are not stably captured. For a general account of the basic ideas as described above, and also the many types of accelerators and variants on the concepts, the reader is referred to basic accelerator texts. Two such texts, which include many useful original references are Livingood (1961) and Kolomensky & Lebedev (1966). The early dates of publication indicate the maturity of this field.

As AG synchrotrons increased in size and energy, it became increasingly important to match the emittance phase space of the incoming particles to the acceptance phase space of the accelerator. This was to ensure the highest beam brightness, particularly as the long acceleration cycle led to low duty ratios. Phase space matching techniques were developed and exploited at the CERN high-energy physics center (Hereward et al., 1956). The transverse acceptance of a simplified AG synchrotron is illustrated in Figure 1.

The need for higher beam brightness led to the invention of the fixed field alternating gradient (FFAG) synchrotron which injected a number of pulses whose phase spaces were spatially separated by the energy increase. This phase space beam-stacking in the FFAG synchrotron further enhanced the usefulness of employing phase space matching concepts (Symon &

Figure 1. Phase-space transformations in an AG synchrotron.

Figure 2. Filamentation of phase space due to nonlinear oscillations.

Sessler, 1956). Phase space matching was also used to increase the efficiency of linear accelerators, and of microwave devices (See **Electron beam microwave devices**). The effect of a mismatch of emittance and acceptance is illustrated in Figure 2 in which a beam with small momentum spread (cross-hatched region) is injected into the acceptance phase space of a synchronous oscillation in a linear accelerator or synchrotron, leading to an increase of the effective phase space area by filamentation (Lichtenberg, 1969).

The development of storage rings greatly increased the importance of keeping the phase space of the injected particles to a minimum. Conceived as a device to obtain high beam brightness, it rapidly became essential for operation of proton accelerators at energies many times the proton rest energy for which the energy in the center of mass of collisions with stationary matter was greatly reduced due to momentum conservation. This led to intersecting storage rings of particles traveling in opposite directions and a very severe requirement of high beam brightness (O'Neil, 1956). Storage rings, which store particles over many machine transits, have required the control of beam spreading. In electron storage rings, the synchrotron radiation which set a limit to electron energy is also effective in reducing the beam phase space (Robinson, 1958). For protons, which are little affected by radiation, stochastic cooling was invented to perform a similar function, a requirement that is essential for proton-antiproton colliders (Van der Meer, 1972).

The development of higher energy accelerators and higher intensity beams has led to new methods of analysis and various problems to be solved. The largest AG synchrotrons include many correcting magnets as well as the bending magnets, quadrupoles, and straight sections. Orbit calculations have required symplectic

integrators to minimize numerical errors, which have involved the development of a Lie algebraic method (Dragt et al., 1988). Various resonances, coupled with machine errors, have led to exploration of resistive and Arnol'd diffusion explanations for beam spreading. Intense beams in electron linear accelerators have produced a pulse-shortening phenomenon that was analyzed as a nonlinear excitation of an electromagnetic mode in the accelerating structure, and methods of suppressing it were devised (Chao, 1993). Space-charge effects that become negligible at highly relativistic energies are again introduced by the beam-beam interaction in intersecting storage ring beams. Analysis of this subtle phenomenon within the environment of the very complicated beam dynamics has led to new exploration of simple mapping models (See **Fermi acceleration and Fermi map**), together with the use of averaging methods to smooth out various more rapid phenomena that do not play an essential role. In linear devices, to go beyond the 30 GeV two-mile long accelerator at SLAC (Stanford), which is field-strength limited, new ideas of structureless acceleration of ions in the wakefields produced by electron beams in plasmas and of electron acceleration, using the wakefield of an intense laser in a plasma, are being actively explored (see Esarey et al. (1996) and other articles in the same issue). The great challenges that face accelerator design above 300 GeV and intersecting beam interactions in storage rings keep a sense of excitement in a mature field. Much of the modern research and new ideas can be reviewed, with references, in Chao & Tigner (1999).

At the same time that the interaction energy has been increased to probe deeper into the fundamental properties of matter, new uses have been found for low-energy accelerators. On the atomic scale, materials are being probed with ultraviolet light and X-rays, using the natural radiation of electrons in circular devices or enhanced radiation employing undulators in combination with accelerators as advanced light sources. These latter devices typically have short period spatially oscillating magnetic fields with the accompanying electron oscillations relativistically doppler shifted to high frequencies (See **Electron beam microwave devices**). At still lower energies, accelerators are being used in various medical applications. Some of the technology-oriented work is treated by Scharf (1989).

PARTICLES AND ANTIPARTICLES

For a good understanding of the physical concept of *antiparticle* and the closely related concept of *charge*, it is important to appreciate how these notions emerged. Therefore, we begin with a brief sketch of the associated history.

In the early days of quantum mechanics, the material world was thought to be built from three elementary particles, namely, the electron, the proton, and the neutron. The idea that there might be associated particles with the same mass and opposite charge (now called antiparticles) first arose from the characteristics of the one-particle Dirac equation. Writing it in Hamiltonian form, the resulting Dirac Hamiltonian has spectrum $(-\infty, -m] \cup [m, \infty)$, where m is the particle mass. The negative part of the spectrum was already considered unphysical by Paul Dirac himself: no such negative energies had been observed, and their presence would give rise, for example, to instability of the electron.

This physical inadequacy of the “first-quantized” description quickly led to the introduction of “second quantization,” as expressed in quantum field theory. In the quantum field theoretic version of the Dirac theory, the problem of unphysical negative energies is cured by a prescription that goes back to Dirac’s hole theory.

Specifically, Dirac postulated that all of the negative energy states of his equation are filled by a sea of unobservable particles. In his picture, annihilating such a negative energy particle with a given charge yields a hole in the sea, which should manifest itself as a new type of positive energy particle with the same mass, but opposite charge. This intuitive idea led Dirac to the prediction that a charged particle should have an oppositely charged partner (its antiparticle).

Ever since, this prediction has been confirmed by experiment, not only for all electrically charged particles, such as the electron and proton, but also for most of the electrically neutral particles, such as the neutron. In the latter case, one still speaks of the particle having a charge, whereas the remaining electrically neutral particles are identical to their antiparticles.

As already mentioned, in the second-quantized Dirac theory no negative energies occur. In the Dirac quantum field, the creation/annihilation operators of negative energy states are replaced by annihilation/creation operators of positive energy holes. This hole theory substitution therefore leads to a physical arena with an arbitrary number of particles and antiparticles with the same positive mass, now called Fock space. (A mathematically precise account can be found in the monograph by Thaller, 1992.)

As it soon turned out, the number of particles and antiparticles in a high-energy collision is not conserved, a phenomenon that can be naturally accommodated in the Fock spaces associated with interacting relativistic quantum field theories. The quantum field theory model that is the most comprehensive description of real-world elementary particle phenomena arose in the early 1970s. During the last few decades, this so-called Standard Model has been abundantly confirmed by experiment.

In spite of these successes, the problem of obtaining nonperturbative insights into the Standard Model remains daunting. This is an important reason why its classical version and various related, but far simpler, classical nonlinear field theories have been, and still are, widely studied. It is a striking and relatively recent finding that within this classical framework, there exist localized, smooth, finite-energy solutions with characteristics that are very reminiscent of particles. The most conspicuous examples in this respect are the soliton field theories, where there exist such particle-like solutions for any given particle number and where the particle numbers and their velocities are preserved in a scattering process.

To be sure, the latter soliton equations arose independently of particle physics. They involve a lower space-time dimension (mostly two), and they have applications in a great many areas that are far removed from high-energy physics. (An early survey that is still one of the best and most comprehensive can be found in Scott et al., 1973.)

Returning briefly to the latter area, there are also various equations, typically within a gauge-theoretic context, where particle-like solutions (instantons, monopoles, vortices, and so on) have been found. A closely related field is classical gravity, where various previously known solutions (such as the Schwarzschild and Kerr black holes) came to be viewed as particle-like solutions, an interpretation strengthened by the occurrence of “many-particle” generalizations.

It should be pointed out that within this nonlinear classical context, there are no explicit many-particle solutions where “creation” and “annihilation” occur. Indeed, it is not even clear how this would manifest itself on the classical level (as compared with the quantum level, where this is a clear-cut matter).

Focusing once again on the notions of charge and particles vs. antiparticles, it is an even more striking fact that these concepts are naturally present within some of the above-mentioned nonlinear field theory models with particle-like solutions. A prime example for gauge theories is given by instanton solutions, which are accompanied by anti-instanton solutions. Roughly speaking, these are distinguished by opposite generalized winding numbers, viewed as charges of a topological nature. More precisely, these localized solutions minimize the energy in certain homotopy classes. This means they are stable under small perturbations.

Turning to soliton field theories, it should be mentioned at the outset that for most soliton equations (for instance, for their most well-known representative, the KdV equation), there exists only one type of soliton, hence no notion of charge. The sine-Gordon field theory is a paradigm for theories where more than one type of soliton occurs. We proceed by using it to exemplify the notions of particle, antiparticle, and charge at the classical level.

The sine-Gordon equation

$$\phi_{xx} - \phi_{tt} = \sin \phi \quad (1)$$

can be obtained as the Euler–Lagrange equation associated with the Lagrangian

$$\mathcal{L} = \frac{1}{2}(\phi_t^2 - \phi_x^2) - (1 - \cos \phi). \quad (2)$$

The corresponding energy functional reads

$$E = \int_R \left[\frac{1}{2}(\phi_t^2 + \phi_x^2) + (1 - \cos \phi) \right] dx. \quad (3)$$

Obviously, the constant solutions

$$\phi_k = 2\pi k, \quad k \in \mathbb{Z}, \quad (4)$$

yield $E = 0$. These are the so-called vacuum solutions.

There exist, however, two distinct classes of nonconstant, time-independent, finite-energy solutions, namely,

$$\phi_{\pm} = 4\arctan(\exp(\pm(x - x_0))), \quad x_0 \in \mathbb{R}. \quad (5)$$

They connect the two vacuum solutions ϕ_0 and ϕ_1 for $x \rightarrow \pm\infty$. The functions $\exp(i\phi_{\pm}(x)) : \mathbb{R} \rightarrow S^1$ have winding numbers ± 1 and may be viewed as generators of the homotopy group $\pi_1(S^1) = \mathbb{Z}$. They are interpreted as one-particle and one-antiparticle solutions (soliton and antisoliton) of the sine-Gordon equation, having charges ± 1 . (By Lorentz invariance, they can be boosted to constant velocity v , with $|v|$ smaller than the speed of light, which is 1 for the units chosen in (1).)

The analogy with electrical charge is strengthened by the existence of soliton–antisoliton bound states, the so-called breathers. More generally, there exist solutions with N_+ solitons, N_- antisolitons, and N_0 breathers, where N_+ , N_- , N_0 are arbitrary integers. These particle numbers and the velocities are conserved in the collision, the nonlinear interaction showing up only in factorized position shifts.

From the viewpoint of elementary particle physics, these findings are regarded as stepping stones for a better understanding of the associated quantum field theory. In particular, the existence of particle-like solutions stabilized by charges of a topological nature is believed to signal the existence of a corresponding stable quantum particle. A lucid survey in which this scenario is expounded is Coleman (1977).

Returning to the sine-Gordon example (also discussed in Coleman, 1977), the above scenario has not only been confirmed, but considerably enlarged: at the quantum level, the sine-Gordon theory yields a model of interacting solitons and antisolitons, whose scattering preserves particle numbers and other characteristics (such as the set of velocities), yielding an explicitly known factorized S -matrix. Thus, the classical picture is essentially preserved under quantization (cf. the review by Zamolodchikov & Zamolodchikov (1979)). It should be stressed that this absence of particle creation and annihilation is highly nongeneric for relativistic quantum field theories; it occurs for only completely integrable soliton type field theories in two space-time dimensions.

The phenomenon of oppositely charged particles and antiparticles with an attractive interaction between them has also come up in a setting quite different from the above field-theoretic one. Consider the classical Hamiltonian

$$H_N = \frac{1}{2} \sum_{j=1}^N p_j^2 + g^2 \sum_{1 \leq j < k \leq N} 1/\sinh^2(x_j - x_k) \quad (6)$$

on the phase space

$$\Omega = \{(x, p) \in \mathbb{R}^{2N} \mid x_N < \cdots < x_1\}. \quad (7)$$

By contrast to the above partial differential equations, most of which are wave equations at face value, the Hamiltonian equations resulting from (6) have, from the outset, a point particle interpretation. To be specific,

they describe N nonrelativistic particles on the line with a repulsive pair interaction.

The special character of this Hamiltonian is already manifest from the scattering to which it leads: the particle velocities are conserved and the position shifts are factorized, just as for solitons. Indeed, Hamiltonian (6) is one version of the completely integrable nonrelativistic Calogero–Moser models. (These are surveyed at the classical and quantum levels in Olshanetsky & Perelomov (1981) and Olshanetsky & Perelomov (1983), respectively.) As pointed out first by Calogero, the substitution $x_k \rightarrow x_k + i\pi$, $k = 1, \dots, N_-$, $N_- \in \{1, \dots, N-1\}$ has the effect of turning the repulsive $1/\sinh^2$ interaction between particles $1, \dots, N_-$ and particles $N_- + 1, \dots, N$ into an attractive $-1/\cosh^2$ interaction. Thus, one obtains an integrable system that can be viewed as describing N_- antiparticles and $N_+ = N - N_-$ particles in interaction.

The nonrelativistic Calogero–Moser systems have been generalized to a relativistic setting, both on the classical and on the quantum levels. Again, there are versions describing particles and antiparticles, with repulsion between like charges and attraction between opposite charges. These versions have been studied at the classical level in Ruijsenaars (1994), where the intimate connection to the sine-Gordon solutions with arbitrary numbers of solitons, antisolitons, and breathers is also detailed. More generally, Ruijsenaars (2001) is a recent survey of this relation between the solitons and antisolitons of the sine-Gordon field theory and the point particles and antiparticles of certain relativistic Calogero–Moser systems, covering both classical and quantum aspects.

PATTERN FORMATION

Beautiful patterns and complex structures spontaneously emerge in a large variety of natural systems. Examples can be found on all length scales, ranging in size from Jupiter's red spot, to water waves, a zebra's stripes, mussel shell patterns, snowflake structures, and down to the nanoscale patterning of the scaffolding that gives stability to individual cells.

How do patterns form? The basic laws of physics should account for all forces driving pattern formation, but even with knowledge of all equations governing the pattern-forming process, it remains difficult to compute what patterns will emerge. A closer look at how the snowflake pattern develops illustrates the key challenges:

(i) Patterns form under nonequilibrium conditions.

In order for an initial seed crystal to form, the air generally has to reach temperatures below the dew and freezing point. Once the seed crystal forms, surrounding air is filled with excess water not in thermodynamic equilibrium. Therefore, the crystal grows under non-equilibrium conditions, which means that the shape of the whole crystal may not obey equilibrium thermodynamics principles such as minimization of free energy. Instead of a spherical shape with minimal surface free energy, complex snowflake shapes emerge. This observation is quite general: patterns form while systems are driven out of equilibrium.

(ii) Patterns can emerge from the competition of processes on various length and/or timescales.

What physical processes govern the pattern-formation process? In the snowflake example, the crystal grows so fast that heat and impurities, rejected from the growing crystal, build up ahead of the crystal-gas interface. They interfere with the growth of the initial spherical crystal and lead to the development of many fine fins. The length scale of the fins is determined by a competition between diffusion, which would lead to many fine fins (for which the diffusion distance becomes shortest) and surface tension, which inhibits very curved interfaces. In general, a variety of physical processes can drive pattern formation including diffusion, chemical reactions, and fluid flow. Patterns emerge from the competition

of processes on different length scales and timescales.

- (iii) *Patterns are history-dependent.* As a non-equilibrium process, pattern formation is usually history dependent and sensitive to the initial conditions, thus it is difficult to predict patterns accurately. Small differences in temperature or water concentration in the atmosphere are amplified in snowflakes, so each snowflake looks distinct, reflecting the atmospheric conditions along the path it traveled. The theory of pattern formation provides insights into how pattern-forming systems can be analyzed and what one may learn about the underlying physical processes from observations of patterns.

General features of the pattern on the other hand, are often related to underlying symmetries in the system and can be predicted. For example, snowflakes often have six spikes, reflecting the symmetry of the anisotropy in the surface tension of ice.

However, each pattern-forming system may be driven by a unique combination of forces: similarities in the patterns may thus only reflect similar symmetries of the underlying equations, timescales, or length scales, not similarities in the underlying physics.

Driven by new mathematical tools, digital imaging, and powerful image analysis tools, numerous experimental and theoretical investigations of pattern-forming systems have been carried out over the past two decades. Cross & Hohenberg (1993) provide an excellent technical introduction into the mathematical concepts of pattern formation. Ball (1999) introduces the field of pattern formation in a non-mathematical way suitable for a broad audience. An update on the field can be found in Gollub & Langer (1999). Below, we briefly describe the basic principles and mathematical tools.

Model Systems of Pattern Formation

Pattern formation implies a change in symmetry. Spontaneous symmetry breaking is particularly evident in fluids, which are structureless in equilibrium but exhibit a surprising variety of patterns under non-equilibrium conditions. Fluid systems have yielded two model systems for detailed studies of pattern formation: surface waves and convection rolls.

Surface waves develop due to either wind or gravitational forces or, for example, when a stone is thrown into the fluid. Under vertical shaking, fluids can exhibit very ordered patterns, such as hexagonal structures as shown in Figure 1. Michael Faraday was the first to analyze ordered surface wave patterns more than a century ago (Faraday, 1831).

Spontaneous symmetry breaking into a patterned state can also be observed when a fluid is driven out

Figure 1. Surface wave patterns in a vertically vibrated fluid. Spirals, stripes, squares, and hexagonal patterns are characteristic of surface waves ("fluid" consists of 170 micron bronze spheres, a few layers deep. Courtesy of D. Goldman, P. Umbanhowar, B. Lewis, and H. Swinney, UT Austin).

of equilibrium through a thermal gradient. If a fluid is heated from below and cooled from above, the fluid near the bottom expands and rises to the top, while fluid near the top cools, contracts, and due to the increased density, drops back to the bottom. This leads to large-scale convection rolls, the so-called Rayleigh-Bénard convection, where streams of rising and falling fluid arrange into complex patterns, similar to the patterns found in surface waves shown in Figure 1.

While diffusion alone tends to create uniform states, Alan Turing suggested that diffusion coupled with chemical reactions may lead to spatial patterns in chemical composition. He speculated that such mechanisms would be sufficient to explain natural patterns such as zebra stripes or the regular shape and arrangement of leaves. An early experimental realization was the Belousov-Zhabotinsky reaction, which involves several intermediate chemical compounds. The original experiments were carried out in a well-stirred container and generated temporal patterns in which the concentration of intermediate components oscillated. Later experiments showed spatial patterns such as stripes and spirals.

Granular systems such as sand or coffee powder also spontaneously form patterns. Under vertical vibration, they form patterns resembling surface waves (see Figure 1). In addition, localized, stationary waves (so-called oscillons) are observed near the onset of surface waves (Umbanhowar et al., 1996). Unlike localized waves in fluids, oscillons do not spread out or dissipate over time. Mixtures of granular matter are also prone to pattern-forming instabilities. For example, when sand and sugar are mixed in a container and poured into a pile, the mixture spontaneously separates into bands under some conditions. Unlike the fleeting structure of surface waves or convection rolls in fluids, patterns in

Figure 2. Pattern formation in nature on many scales: (a) Crystal growth pattern (rime on a windshield). (b) Mussel shell pattern (*Conus textile*, Courtesy of P. Egerton) (c) Scaffolding of a cell during cell division (Spindle assembly in *Xenopus* extracts. Microtubules (long) and DNA (rings), Courtesy of R. Ohi and T. Mitchison, Harvard Medical School, Boston).

granular flows can create lasting impressions such as bands of sugar and sand in a mixture, or sand ripples and sand dunes in wind-driven flows.

In solids, snowflakes are a well-known pattern (see Figure 2a) which we have discussed above. Similar patterns can be found in alloys and polymer blends, though they are hidden within the material micro- or nanostructure. Patterns in solids are technologically important, because they can determine material strength and flexibility.

Biological systems offer a rich variety of patterns. On large scales, patterns such as zebra stripes and

mussel shell patterns (Gierer & Meinhard, 1972) (see Figure 2b) help animals blend in or send signals of intimidation or attraction. On a small scale, the microscopic mechanical structure within cells contains ordered arrangements of microtubules and other filaments, which assist, for example, in cell division (see Figure 2c).

Stability and Bifurcations

The first prerequisite for the emergence of patterns from a spatially uniform state is a symmetry-breaking instability. A linear stability analysis indicates whether a given set of equations is prone to a symmetry-breaking instability. For example, we start with a set of functions $u(t)$:

$$\frac{du}{dt} = f(u). \quad (1)$$

To assess the stability of a state u_0 , we linearize around that state $u = u_0 + \delta$. This yields an equation for the perturbation δ :

$$\frac{d\delta}{dt} = \left. \frac{df(u)}{du} \right|_{u_0} \delta. \quad (2)$$

The state u_0 is linearly stable against perturbations if δ shrinks for any shape of the initial perturbation and unstable if it grows. To test for all possible perturbations, δ can be decomposed into Fourier modes $\delta = \delta_q \exp(iq \cdot x)$. This indicates the range of wave numbers (q) that are unstable.

Generally, pattern-forming systems become unstable when they are driven further from equilibrium. The transition point toward instability is called marginal stability. In the marginally stable state, perturbations of one, or a few, wave numbers neither grow nor decay; all other perturbations decay.

When parameters are changed further, the system will become unstable for a range of wave numbers (sometimes including $q = 0$). In the example of crystal growth, a planar crystal growth front is stable for small q (due to diffusion) and for large q (due to surface tension), but unstable for a range of intermediate q .

Once the perturbations grow, the linear approximation fails since δ will diverge, and other approaches are needed to predict patterns, but the range of unstable wave number is often a rough indicator of the characteristic length scales of the final patterns.

Model Equations

Beyond linear instability, modeling of pattern-forming systems becomes interesting: rather than going back to the full equations for the pattern-forming system, which are often too complex to be simply studied numerically or analytically, model partial differential equations have been developed to describe the main qualitative features

of patterns, and to highlight the universal features of many pattern-forming systems. They are discussed in great detail, for example, in the excellent review by Cross & Hohenberg (1993). Here we list the main equations.

The (complex) Ginzburg–Landau equation is an amplitude equation with an expansion in amplitudes and gradient terms. The equation applied, for example, to a two-dimensional plane can yield similar patterns as the vibrated fluid shown in Figure 1: squares, hexagons, and stripes. The equation provides insight into which gradient or higher-order terms must dominate in specific patterns. Long wavelength instabilities such as the Eckhaus instability are common and limit the range of stable patterns to a smaller range of wave numbers than the range of linearly stable wave numbers.

Other equations include the Swift–Hohenberg equation and the Kuramoto–Sivashinsky equation, which have been solved in various geometries and for different boundary conditions and parameter ranges. They provide a rich set of patterns and dynamical instabilities.

Experimentally and in simulations, the best model system has proven to be surface waves and Rayleigh–Bénard convection. The stability phase diagram of the convecting fluid—the range of stable wave numbers as a function of a measure of fluid convection such as the Rayleigh number—exhibits a region of stability, the so-called Busse balloon, bounded by various instabilities such as the Eckhaus instability, a zig-zag instability, or a cross roll instability. The range of stable patterns and the instability boundaries have been verified through extensive experiments.

Slightly different are equations that describe patterns in excitable media, which are often used to mimic biological processes. Reaction-diffusion equations yield wave fronts or spiral waves. Again, basic symmetries of the underlying processes dictate what patterns can occur, and the stability boundaries are crucial.

Finally, it should be noted that real patterns have boundaries and defects, which can strongly affect pattern selection and stability. Modeling defects and boundaries appropriately can be difficult, since it may only introduce small perturbations that change the system over long timescales (which are often beyond the reach of simulations). Recently, controlled experiments where defects are implanted deliberately into patterns have begun to allow quantitative tests of theories, but this work is only beginning.

Challenges for the future include application of these insights to real pattern forming systems, for example, to suppress or exploit crystal growth instabilities in the semiconductor industry. General theoretical descriptions of pattern formation in networks such as neural networks remains one of the open challenges.

PEIERLS BARRIER

As a localized entity such as an electron, hole, polaron, soliton, or dislocation moves through a discrete lattice, it often experiences a potential barrier between one unit cell and the next. Called a Peierls barrier after the famed German/British physicist Rudolph Peierls, such potential barriers plays a key role in lattice dynamics.

More precisely, a Peierls barrier characterizes the dependence of the energy, $E(\vec{n})$, of a stationary localized entity (LE) on its position, $\vec{n}$, in a periodic lattice. The Peierls barrier, is the function $E(\vec{n}) - E_0$, where $E_0 = \min E(\vec{n})$ is the ground state energy of the LE. Because of lattice periodicity the barrier must be a periodic function with a period equal to the lattice constant a . Minima of the Peierls barrier correspond to stable positions and maxima to unstable positions. The barrier height $\Delta E = \max[E(\vec{n}) - E_0]$ is often called the pinning energy. To propagate along the chain, the LE must be activated with energy exceeding ΔE . For smaller energies, the LE vibrates near minima of the Peierls barrier, and for larger energies it can overcome the Peierls barrier and move through the lattice. The presence of a Peierls barrier also leads to the appearance of new eigenvalues corresponding to periodic oscillations of an LE near a minimum of the Peierls barrier.

The notion of the Peierls barrier goes back to the first quantitative explanation of the mechanism of plastic flow via the motion of dislocations in a lattice (Peierls, 1940; Naborro, 1967). From the perspective of the continuum theory of elasticity, a dislocation is an LE that involves a discontinuity in the displacement field, leading to singularities in strains and stresses. Peierls and Naborro showed how to overcome these artifacts of continuum idealizations by distributing the sharp discontinuity over a finite region, as in the one-dimensional nonlinear continuum Frenkel–Kontorova model of dislocation.

The dynamic influence of a Peierls barrier is greatest when the size of the LE is about equal to the lattice periodicity. Failure to include it in theoretical formulations can lead to erroneous calculations. When modeling the dynamics of protonic solitons in chains of hydrogen bonds, for example, inclusion of the Peierls barrier is necessary to find the temperature dependence of soliton mobility (Savin & Zolotaryuk, 1991).

Let us consider in more detail an autolocalized state of a quantum particle in a lattice (or molecular chain). In a simplified model, the dynamics of such a quasiparticle is described by the system of equations

$$i\hbar\dot{\phi}_n = \chi u_n \phi_n - J(\phi_{n-1} + \phi_{n+1}), \quad (1)$$

$$m\ddot{u}_n = -K u_n - \chi |\phi_n|^2, \quad (2)$$

where $-\infty < n < +\infty$ is an integer, $\{\phi_n\}$ is a complex-valued wave function normalized by the condition

$$\sum_n |\phi_n|^2 = 1, \quad (3)$$

where u_n is the intramolecular displacement of the lattice, and χ , J , m , and K are parameters of the exciton-phonon interaction: energy of resonance or exchange interaction between neighboring lattice sites, reduced mass of the molecules, and stiffness of intermolecular interaction. Neglecting the inertia of intramolecular displacements implies that $u_n = -\chi |\phi_n|^2 / K$, whereupon Equations (1) and (2) reduce to a discrete nonlinear Schrödinger equation (DNLS), which can be written as

$$-i\frac{d\phi_n}{d\tau} = \phi_{n-1} + \phi_{n+1} + g\phi_n |\phi_n|^2, \quad (4)$$

where $\tau = Jt / \hbar$ and $g = \chi^2 / KJ$ is a dimensionless parameter of nonlinearity.

In the continuum limit, Equation (4) reduces to the nonlinear Schrödinger (NLS) equation, which is integrable. In this limit, the Peierls barrier does not play any role because an envelope soliton can propagate freely along the chain. For the discrete model, which is not integrable, the situation is quite different.

A stationary autolocalized state of the quasiparticle can be found numerically by minimizing

$$H = -\sum_n \varphi_n \varphi_{n+1} + \frac{1}{4} g \varphi_n^4,$$

Figure 1. Stationary autolocalized state of the quantum quasiparticle with integer (curve 1) and half-integer (curve 2) centers of symmetry. Curve 3 (below) shows the Peierls barrier, i.e., the dependence of the energy of the stationary state E on the position of the center n . Nonlinear parameter $g = 3$.

subject to the constraint of Equation (3), where φ_n is the real-valued amplitude of quasiparticle wave function on n th site. If $\{\varphi_n\}_{n=-\infty}^{+\infty}$ is the solution of the minimization problem, the energy and position of the LE are $E = H$ and

$$\bar{n} = \sum_n n \varphi_n^2,$$

respectively.

Stationary states of quasiparticle have two types of symmetry. First is a solution with integer center of symmetry $\varphi_{n_0+n} \equiv \varphi_{n_0-n}$. In other words, the center of the LE is in one of the lattice sites. Second is a solution with half-integer center of symmetry, where the center of excitation is midway between two lattice sites ($\varphi_{n_0+n} \equiv \varphi_{n_0+1-n}$, $\bar{n} = n_0 + \frac{1}{2}$). The ground state is of the first type and corresponds to a minimum of the Peierls barrier. The second type is unstable and corresponds to a maximum of the Peierls barrier.

Numerical solution of the minimization problem allows one to find the energy profile of a Peierls barrier, as plotted in Figure 1. This profile has a sine-like character with minima at integer points and maxima in half-integer points. The height of the Peierls barrier depends on the value of nonlinear parameter g . If the nonlinearity parameter $g \rightarrow 0$, the size of the LE grows without bound, and the pinning energy ΔE goes monotonically to zero. One can calculate Peierls barriers analytically using the method of variational functions (Kuprievich, 1985).

Note that a specific discretization of the continuum NLS equation (Ablowitz & Ladik, 1976) leads to a discrete integrable system. In this case, the ground state energy does not depend on the position of the LE and the Peierls barrier is absent.

PENDULUM

With a history covering many centuries, the pendulum has been of primary importance in the development of physics. It is well known that in the 17th century, Dutch experimental physicist Christiaan Huygens discovered the synchronization phenomenon while studying pendulum clocks (Huygens, 1673). Using a pendulum as an example, Huygens formulated the conservation law for mechanical energy. In the 18th century, the French scientist Jean Charles Borda suggested using a pendulum for measuring the acceleration of gravity (Borda, 1792), and Wilhelm Bessel used a pendulum for an accurate verification of the equality of inertial and gravitational masses. There are many other applications of pendula for physical measurements; for example, a pendulum with a randomly vibrated suspension axis has turned out to be a good model for control of turbulence in subsonic submerged jets (Landa, 1996).

Two models of a pendulum are well known—mathematical and physical. The mathematical pendulum is defined as a ball suspended by a weightless thread in vacuum (Figure 1a). It is described by the equation

$$\ddot{\varphi} + \omega_0^2 \sin \varphi = 0, \quad (1)$$

where φ is the pendulum angle of deviation, $\omega_0 = \sqrt{g/l}$ is the angular frequency of small oscillations, g is the acceleration due to gravity, l is the thread length, and dots indicate derivative with respect to time. The physical pendulum can be defined as a body moving about a fixed horizontal axis O (Figure 1b).

Taking account of air friction, the motion equation for such a body is

$$I\ddot{\varphi} + h\dot{\varphi} + mga \sin \varphi = 0, \quad (2)$$

where I is the body's moment of inertia, h is the friction factor, m is the body's mass, and a is the distance between the axis and the body's center of gravity.

Equation (1) belongs to the class of nonlinear conservative (Hamiltonian) systems, whereas Equation (2) is a dissipative system. Solutions of these equations

Figure 1. Schematic image of (a) mathematical pendulum and (b) physical pendulum.

Figure 2. (a) Phase portrait of pendulum oscillations in the phase plane; (b,c) the time dependencies of the pendulum phase coordinates φ and $\dot{\varphi}$ at the motion of a representative point along a separatrix.

can be conveniently analyzed with the phase plane $\varphi, \dot{\varphi}$. We illustrate this for Equation (1).

Using the energy conservation law, we obtain an equation for a trajectory in the phase plane $\varphi, \dot{\varphi}$ in the form

$$\frac{ml^2 \dot{\varphi}^2}{2} + mgl(1 - \cos \varphi) = E, \quad (3)$$

where E is the total pendulum energy. For $E < 2mgl$, Equation (3) describes closed trajectories corresponding to pendulum oscillations about the stable equilibrium position ($\varphi = 0$), and for $E > 2mgl$, nonclosed trajectories corresponding to the rotation of the pendulum (Figure 2a). These two kinds of trajectories are separated by peculiar trajectories passing through singular saddle points ($\dot{\varphi} = 0, \varphi = \pm \pi, \pm 3\pi, \dots$). Such trajectories are said to be *separatrices*. Because values of φ differing from each other by 2π are physically indistinguishable, the phase plane shown in Figure 2a can be rolled into a cylinder.

In general, solutions of Equations (1) and (3) are Jacobi elliptic functions, but more simple solutions can be obtained in the case of small oscillations ($E \ll mgl$) and in the case when $E = 2mgl$ (this value of E

corresponds to the motion of a representative point along a separatrix). In the latter case, Equation (3) is split into two equations:

$$\dot{\varphi}_{\pm}(t) = \pm 2\omega_0 \cos \frac{\varphi}{2}. \quad (4)$$

By integrating (4) we find

$$\varphi_{\pm}(t) = \pm \left(4 \arctan e^{\omega_0 t} - \pi \right). \quad (5)$$

The time dependencies of $\varphi = \varphi_{\pm}$ and $\dot{\varphi} / \omega_0 = \dot{\varphi}_{\pm} / \omega_0$ are shown in Figure 2b and c. These solutions play an important part in soliton theory.

In the case of sufficiently small oscillations, when $\sin \varphi \approx \varphi - \varphi^3 / 6$, Equation (1) reduces to the Duffing equation

$$\ddot{\varphi} + \omega_0^2 \left(1 - \frac{\varphi^2}{6} \right) \varphi = 0. \quad (6)$$

The general solution of Equation (6) is

$$\varphi = A \operatorname{sn}(\Omega t, k), \quad (7)$$

where sn is a Jacobi elliptic function of modulus $k = \sqrt{1/12} A / \Omega$, and $\Omega = \omega_0 \sqrt{1 - A^2 / 12}$. Solution (7) is valid for $A \leq \sqrt{6}$, when $k \leq 1$. This constraint is certainly fulfilled because Equation (6) follows from (1) only for $A < 1$. Solution (7) describes periodic oscillations of period $4K(k) / \Omega$, where $K(k)$ is the full elliptic integral of the first kind. It follows from this that the period of oscillations increases with increasing amplitude. Such a property inherent in nonlinear systems is called anisochronism. It should be noted that Galileo was the first to discover the isochronism of small pendulum oscillations.

If a pendulum consisting of an iron ball suspended by a thread of length l is placed between the opposite poles of a magnet, its behavior essentially changes (Landa, 1996, 2001). Approximating the magnetic force acting on the ball by $F(\varphi) = ml(a_1\varphi - b_1\varphi^3)$ and restricting ourselves to small oscillations of the ball, then the pendulum angular deviation φ obeys the following approximate equation:

$$\ddot{\varphi} - (a - b\varphi^2)\varphi = 0, \quad (8)$$

where $a = a_1 - \omega_0^2$, $b = b_1 - \omega_0^2 / 6$, $\omega_0^2 = g / l$. In the case that $a_1 > \omega_0^2$ ($a > 0$), the equilibrium position $x = 0$ becomes aperiodically unstable (the corresponding singular point $\varphi = 0$, $\dot{\varphi} = 0$ in the phase plane $\varphi, \dot{\varphi}$ becomes of saddle type). If, in addition to this, the inequality $b_1 > \omega_0^2 / 6$ holds, two stable equilibrium positions with coordinates $\varphi_{1,2} = \pm \sqrt{a/b}$ appear. These equilibrium positions correspond to singular points of center type. But if $b_1 < \omega_0^2 / 6$ and $a > 0$, then the ball adheres to one of the magnet poles. Equation (8) describes a so-called two-well oscillator, which is the subject of recent widespread interest in connection with stochastic and vibrational resonances (Landa, 2001).

If a pendulum is suspended from a uniformly rotating shaft, it can execute self-oscillations. Such a pendulum was discovered by William Froude and mentioned in the famous treatise by Lord Rayleigh (Rayleigh, 1877). Rayleigh showed that oscillations of such a pendulum are approximately described by an equation which came to be known as the Rayleigh equation. A controlled Froude pendulum was suggested by Neimark to be a model of stochastic oscillations (Neimark & Landa, 1992).

PERCEPTRON

The perceptron is one of the earliest computational models inspired by the human brain. Developed by Frank Rosenblatt from 1959–1962, the perceptron model is a parallel, distributed processing network intended to provide a means of modeling the capabilities and properties of the brain at a very simplified level (Rosenblatt, 1962).

Artificial neurons as mathematical processing elements of neurological (or artificial neural) networks were described earlier by Warren McCulloch & Walter Pitts (1943). Also earlier was the work of Donald Hebb, which presented a principal of learning or self-organization in neural networks (Hebb, 1949). The perceptron brought these concepts together by providing an algorithm for adjusting the parameters or weights of the network to learn to perform mappings or predicates. This model was implemented in analog electrical hardware by Rosenblatt and colleagues as the Mark I Perceptron and as such was the first neurocomputer to perform useful functions (Block, 1962). Accepting that biological brains possess “natural” intelligence, developing

Figure 1. (a) General perceptron model. (b) Single perceptron unit.

computational models inspired by the brain represents one approach toward artificial intelligence.

The general perceptron model consists of a retina, associator units, and response units (see Figure 1a). The retina provides sensory inputs connected (many-to-many and at random) to a layer of associator units. The associator outputs are connected to response units. Connectivity can be sparse, and both associator and response units can be connected to other units in the same layer. An associator unit becomes active if its total input exceeds some threshold value and propagates a signal to the response units. This model appears to have the essential features to begin studying brain function (learning, pattern recognition, memory, generalization) in terms of brain structure.

A perceptron unit computes a threshold function of the values presented via its input connections

$$y = \begin{cases} 1 & \text{if } \sum_{i=1}^n w_i x_i > \theta, \\ 0 & \text{otherwise,} \end{cases} \quad (1)$$

where x_i is the value of the i th input signal. Each input connection is weighted by a real-valued weight w_i , and θ determines the threshold value. Geometrically, the perceptron unit implements a hyperplane in n -dimensional input space, where input vectors lying on one side of the line will result in an output of 1, and input vectors on the other side of the line will result in an output of 0. The position of the hyperplane is determined by the values of the weights and thresholds (zero threshold implies a hyperplane passing through the origin).

The simple perceptron unit provides a useful, simplified realization of the above model which can be implemented and trained to perform useful functions (Figure 1b). A set of inputs $X = \{x_1, \dots, x_n\}$ are provided to a layer of associator units that compute a fixed value $\varphi(X)$. These values are then combined at the response unit to produce a binary output $\Psi(X)$. The response unit

is adaptive in that there is an adjustable weight parameter α_i associated with each of its input connections. The output of the response unit Ψ is calculated as

$$\Psi = 1 \text{ if } \sum_{i=1}^n \alpha_i \varphi_i(X) > \theta, \quad (2)$$

$$\Psi = 0 \text{ otherwise,} \quad (3)$$

where θ is a threshold value. The simple perceptron can compute any linear threshold function of the $\varphi_i(X)$ given appropriate values of the weights α_i and θ .

Given a set of data points in n -dimensional input space, labeled with desired (0 or 1) output values, Rosenblatt provided a rule for iteratively learning (modifying) the perceptron weights and thresholds, such that the outputs of the perceptron would match the desired output values. He also proved the convergence of the learning rule in a finite number of steps, provided that the perceptron has the capacity (ability) to learn an adequate linear threshold function. That is, if the n -dimensional (0,1)-labeled data is separable by an $(n - 1)$ -dimensional hyperplane in the input space, the perceptron can learn or be trained to find such a hyperplane.

An adaptive threshold value can be conveniently implemented by replacing θ with an additional input x_0 , that always takes the value 1, and an adaptive weight w_0 . Given input values and the desired (correct) value d for the output, the output of the model is computed from the inputs and the weights are adapted as follows:

$$\alpha_i = \begin{cases} \alpha_i & \text{if } d = y(X), \\ \alpha_i + x_i & \text{if } d = 1 \text{ and } y(X) = 0, \\ \alpha_i - x_i & \text{if } d = 0 \text{ and } y(X) = n1. \end{cases} \quad (4)$$

If the threshold function is changed to a continuous, differentiable function, it becomes possible to formulate a cost function for learning that is a differentiable function of the weight values. For example, a sigmoidal function is commonly used to approximate the threshold function. The delta rule can then be used to train the unit via an iterative gradient descent (Widrow & Hoff, 1960). Widrow and Hoff developed the delta (or Least Mean Squared) rule in the context of ADALINES (ADaptive LInear NEurons), which are equivalent to McCulloch–Pitts neuron models with the bias weight (Widrow & Lehr, 1990). A quadratic error function resulting from the sum of squared error terms is used, making it possible to guarantee convergence of the delta rule under appropriate assumptions. In contrast, the perceptron learning rule does not converge if the data is nonlinearly separable.

In general, a perceptron may consist of a layer of k of the above perceptron units, each of which is fully connected to same set of inputs but has its own output. Both Rosenblatt's perceptron learning rule and the delta rule can be straightforwardly extended to train such a network.

The inability of single-layer perceptron to implement nonlinearly separable mappings and the lack of a procedure for training a multilayer perceptron model led to a lull in progress in the field for many years (Minsky & Papert, 1990). Recently, the back-propagation algorithm led to a resurgence of interest in the multilayer perceptrons and artificial neural network models. Such models have been very successfully applied to a wide range of data-driven learning tasks such as pattern recognition, classification, regression, and prediction (Haykin, 1999).

PERCOLATION THEORY

For random site percolation, each site of a large lattice is randomly occupied with probability p and empty with probability $1 - p$. A cluster is a set of neighboring occupied sites. A spanning cluster extends from one end of the sample to the opposite end. Percolation theory (PT) deals with the number and properties of spanning and nonspanning clusters as a function of p and of the cluster size s : the number of occupied sites in the cluster. Alternative variants are bond percolation where all sites are occupied but bonds between neighbor sites exist only with probability p . A cluster then is a set of sites connected directly or indirectly by existing bonds. One may also remove the lattice structure and place possibly overlapping circles on a piece of paper (or spheres in three dimensions). Instead of random variables, one can also study correlated percolation, such as Ising models where up spins are identified as occupied and down spins as empty sites. The following results are expected to be also valid for these variants as long as the corre-

lations have a finite spatial extent (i.e., not at the Curie point of Ising models) (Stauffer & Aharony, 1994).

In 1941, Paul Flory published the first percolation theory (ignoring cyclic links and excluded volume effects). Physicists call this the Bethe lattice or mean field approximation, and it becomes exact for very high dimensions but is inaccurate in its critical behavior for the two or three dimensions we are mostly interested in. Percolation theory was continued by Stockmayer (1943), applied to immunology at the beginning of the 1950s, and a few years later, put onto square lattices by Broadbent & Hammersley (1957). The first computer simulations were published around 1960, and in 2001, these reached 4 million times 4 million sites (Tiggemann, 2001) and even larger lattices in Maloney & Pruessner (2003), using the Hoshen–Kopelman algorithm (Stauffer & Aharony, 1994). Exact polynomials for the number $n_s(p)$ of clusters of s sites were found for small and intermediate s , and exact results for many thresholds p_c and critical exponents are known in two dimensions.

For small p , we have only small clusters, and for p near unity, nearly the whole system forms a huge spanning cluster coexisting with rare small clusters. Thus, there is a sharp critical threshold p_c , where with increasing p for the first time, a spanning cluster appears in a very large lattice. For random site percolation on the triangular lattice with six neighbors or for random bond percolation on the square lattice, we have $p_c = \frac{1}{2}$, while for the square site problem, numerical estimates give $p_c \approx 0.5927462 \dots$ and $p_c \approx 0.31161 \dots$ for simple-cubic random site percolation. (Dimensions much higher than two and three were recently investigated by Grassberger (2003). Random percolation in one dimension has $p_c = 1$.) Only in infinite lattices are these thresholds defined as infinitely sharp.

Quantities of interest besides n_s are the probability $R(p)$ to have a spanning cluster, the fraction P_∞ of sites in the infinite (spanning) cluster, the mean cluster size

$$S = \frac{\sum_s n_s s^2}{\sum_s n_s} \quad \text{or} \quad \sum_s n_s s^2, \quad (1)$$

the average cluster radius R_s , and the characteristic length ξ defined best through $\xi^2 = \sum_s R_s^2 n_s s^2 / \sum_s n_s s^2$ among other properties. (For $p > p_c$ in these sums, the spanning cluster is omitted.) Figure 1 shows S versus p , for random site percolation on nearest-neighbor simple-cubic lattices. From scaling laws or renormalization group arguments, the critical phenomena for large clusters and small $p - p_c$ are

$$\begin{aligned} n_s &\propto s^{-\tau} f[(p - p_c)s^\sigma], \\ n_s &\propto (p - p_c)^\beta, \\ S &\propto |p - p_c|^{-\gamma}, \\ \xi &\propto |p - p_c|^{-\nu}, \\ R_s(p = p_c) &\propto s^{\sigma\nu} \end{aligned} \quad (2)$$

Figure 1. Mean cluster size from Equation (1) for seven nearest-neighbor simple-cubic lattices $1000 \times 1000 \times 1000$ (+) compared with $100 \times 100 \times 100$ (line).

with the critical exponents given by Greek letters.

The first of these equations (Stauffer & Aharony, 1994) leads to Fisher's scaling laws $\beta = (\tau - 2)/\sigma$, $\gamma = (3 - \tau)/\sigma$, while additional hyperscaling assumptions valid for dimensionality d below six give $d\nu = \gamma + 2\beta = (\tau - 1)/\sigma$. The fractal dimensionality D of clusters at the percolation threshold, defined (Bunde & Havlin, 1996) through $s \propto R_s^D$, is then

$$D = 1/(\sigma\nu) = d - \beta/\nu = d/(\tau - 1). \quad (3)$$

Because an infinite cluster first appears for increasing p at $p = p_c$, it is plausible that for p slightly below p_c , we see finite but very large clusters; thus, the mean cluster size S diverges for $p \rightarrow p_c$ in an infinite system. In a finite system, S remains finite but the position of its maximum moves towards p_c and its height towards infinity, for system size $\rightarrow \infty$ (see Figure 1). The relation of its critical exponent γ with σ and τ can be easily derived from the above assumption for n_s by approximating the sum for S through an integral over s .

Flory's approximate solution is valid for the critical exponents only above six dimensions: $\beta = \gamma = 2\nu = 2\sigma = 1$, $\tau = \frac{5}{2}$, $D = 4$; the above scaling function f is then a Gaussian. For the more relevant case of $d = 2$, we have $\beta = 5/36$, $\gamma = 43/18$, while in three dimensions $\beta \simeq 0.42$, $\gamma \simeq 1.79$ with the other exponents following from the above scaling laws. The scaling function f is no longer a Gaussian but has a maximum below p_c ; the cluster numbers n_s away from p_c decay as $\log(n_s) \propto -s$ above p_c and as $\propto -s^{1-1/d}$ below p_c . For $p < p_c$, the fractal dimension in three dimensions is $D = 2$, one of the rare cases where an exact solution was found in three but not in two dimensions.

Besides computer simulation, small-cell renormalization group methods also give reasonable approximations for thresholds and critical exponents. One divides

the infinite lattice into cells of linear dimension b such that the cell centers themselves again form a lattice of the same type as the original lattice. A cell is occupied if the original occupied sites form a cluster spanning this cell. In this way, the original occupation probability p is renormalized into the cell occupation probability $p' = R(p)$. One may iterate this renormalization by computing $p'' = R(p')$ and then $R(p'')$ and so on. The fixed point p^* of this transformation obeys $p^* = R(p^*)$ and approaches, for large b , the true percolation threshold p_c . At this fixed point, the derivative $dR(p)/dp$ is related to the critical exponent ν . However, in contrast to many renormalization group publications, $R(p_c)$ is not equal to p_c (Ziff, 1992).

Some mathematical theorists in the 1980s claimed that the infinite cluster is unique, but this is not true at $p = p_c$ where several spanning clusters can coexist (Aizenman, 1997). Even above p_c in very elongated rectangles, one may find several clusters spanning in the short direction.

How do these theoretical and numerical results compare with applications and reality? Because the percolation thresholds p_c depend on the lattice structure, one should not expect them to agree with off-lattice experiments, but the exponents are more "universal" and should agree when comparing reality with PT. There are many applications (Sahimi, 1994) including flow in porous media, conductor-insulator mixtures, elasticity of composite materials, and breakdown of the internet. Sputtering metal drops onto a plane offers a particularly accurate realization of percolation.

Flory invented the percolation theory to describe the sol-to-gel transition of branched polymers, known from boiling your breakfast egg. But only half a century later was it experimentally confirmed that the gelation exponents are indeed those of three-dimensional lattice percolation theory.

Another application of percolation clusters is to speed up computer simulations of Ising models (ferromagnets) near their Curie point, using the clusters of correlated bond percolation formed by up spins connected by bonds with probability $p = 1 - \exp(-2J/k_B T)$. Flipping whole clusters instead of single spins equilibrates the system much faster. (In this Fortuin-Kasteleyn-Coniglio-Klein-Swendsen-Wang theory (Stauffer & Aharony, 1994), T is the absolute temperature, k_B the Boltzmann constant, and J the interaction energy such that $2J$ is the energy to change an isolated pair of parallel spins into antiparallel.) For example, right at the Curie point in a two-dimensional $L \times L$ lattice, the relaxation time no longer increases as $L^{2.17}$ but only as $\log(L)$ if these percolation clusters, instead of single spins, are flipped.

The above application stems from the relation between percolation clusters and the q -state Potts model ($q = 2$ is the Ising model again). The partition

function of this Potts model is $Z = \langle q^N \rangle$, where N is the total number of bond percolation clusters at the above $p = 1 - \exp(-2J/k_B T)$ and $\langle \dots \rangle$ denotes the average over many realizations. Taking the limit $q \rightarrow 1$, we get $\ln(Z) / \ln(q) \rightarrow \langle N \rangle = \sum_s n_s$, recovering random percolation which is thus a $q \rightarrow 1$ Potts model.

Percolation is also a convenient teaching example. Filling a small triangular lattice at $p = p_c = \frac{1}{2}$ by throwing coins reveals in the classroom fractals, statistical errors, and (in the resulting number of isolated sites) strong systematic errors from the lattice boundaries.

PERIOD DOUBLING

Like many terms used in the nonlinear sciences, *period doubling* has more than one meaning. Well known is the response of a system at half the driving frequency, due to nonlinear coupling. Probably the earliest observation of period doubling was by Michael Faraday, in his investigations of shallow water waves (Faraday, 1831, arts. 98–101). The phenomenon was also investigated by Lord Rayleigh (Rayleigh, 1887). He wrote of an example:

in which a fine string is maintained in transverse vibration by connecting one of its extremities with the vibrating prong of a massive tuning-fork, the *direction of motion of the point of attachment being parallel*

to the length of the string the string may settle down into a state of permanent and vigorous vibration whose *period is double that of the point of attachment*.

A more everyday example is the fact that a child may set a swing into transverse motion by standing on the seat and moving up and down at twice the natural frequency. Such phenomena are in the province of *harmonic generation* and *parametric amplification* and are not treated in this entry.

Period doubling (as discussed in this entry) is the most common of several *routes to chaos* for a nonlinear dynamical system.

The dynamics of natural processes, and the nonlinear equations used to model them, depend on externally set conditions, such as environmental or physical factors. These take fixed values over the development of the system in any particular instance, but vary from instance to instance. Expressed as numerical quantities, such factors are called parameters, and their role is vital. Often, increasing a parameter increases the nonlinearity. The simplest example is the logistic model (May, 1976)

$$x_{n+1} = r x_n (1 - x_n), \quad (1)$$

a discrete system with state variable x_n and parameter r ; n is the generation. (If x represents population, then r characterizes the underlying growth rate.)

For period doubling, it is sufficient to vary a single parameter. Over some range, the system may have a periodic attractor, that is, a periodic orbit that attracts neighboring orbits. Typically, the stability (attraction) decreases as the parameter increases, changing to instability (repulsion) at a critical value. This is a bifurcation, or change of structure, of the orbit. In period doubling, this change is accompanied by the “birth” of a new attracting period-doubled orbit, in which the system alternates between two states. In biological systems, these are known as alternans (Glass & Mackey, 1988). In the period-doubling route to chaos, each new periodic attractor loses its stability with increasing parameter value, whereupon the next period-doubled attractor is born. If the original attractor was a fixed point, this generates orbits of period 1, 2, 2^2 , 2^3 , ... called the main period-doubling cascade.

A surprising *universality* was discovered by Mitchell Feigenbaum. In part, it relates to the sequence of parameter values at which successive period doubling occurs. Label the first by r_1 , the second by r_2 , and so on, and let the cascade end at the value r_∞ . The differences $(r_\infty - r_n)$ decrease to zero; the surprising fact is that the ratios $(r_\infty - r_n)/(r_\infty - r_{n+1})$ converge to a universal constant δ , which takes the same value $\delta \approx 4.669202\dots$ for all maps with a quadratic maximum (Feigenbaum, 1978). There is a second universal constant, $\alpha \approx 2.502908\dots$, measuring the relative spatial scale of the orbits, which also becomes increasingly fine.

<i>n</i>	Logistic		Hénon	
	<i>r_n</i>	$\left(\frac{r_{n+1}-r_n}{r_{n+2}-r_{n+1}}\right)$	<i>a_n</i>	$\left(\frac{a_{n+1}-a_n}{a_{n+2}-a_{n+1}}\right)$
1	3.000000000		0.367500000

Table 2. Selected experimental data on period doubling.

Numerical data for two main period-doubling sequences is given in Table 1. Columns 2–3 display data for the logistic map,

$$x_{n+1} = 1 - ax_n^2 + y_n, \qquad y_{n+1} = bx_n. \qquad (2)$$

columns 4–5 for its two-dimensional cousin, the Hénon map. For Table 1, the parameter b has been kept constant. Experimental data has also been obtained in quite a few systems (Cvitanović, 1989); a selection is shown in Table 2. To appreciate the experimental difficulty involved, remember that for each successive period doubling, the significance of errors increases five-fold while the complexity of the dynamics doubles.

The mechanism for period doubling is already implicit in the fact that it is also known as a “flip bifurcation.” Stability of a fixed point x^* of a smooth one-dimensional map f is the simplest case for theory. Consider a nearby point x that maps to x' . Linear approximation gives

$$(x' - x^*) \approx f'(x^*) \cdot (x - x^*).$$
 (3)

This shows (and exact analysis confirms) that the fixed point is stable if $-1 < f'(x^*) < 1$ and unstable if $f'(x^*) < -1$ or $f'(x^*) > 1$. Successive iterates flip from side to side for negative $f'(x^*)$, so period doubling occurs at $f'(x^*) = -1$. For higher-dimensional systems, stability is determined by the eigenvalues of a matrix of partial derivatives; the occurrence of an

Figure 1. Mechanism: f and f_2 for $r = 2.8$ (left) and $r = 3.2$ (right).

eigenvalue $\lambda = -1$ leads to period doubling. Because $x_{n+2}^* = x_n^*$ for the new orbit, period doubling is connected with double iteration, controlled by the second composition map $f_2(x) = f(f(x))$. Elementary calculus shows that if f satisfies the two conditions

$$f(x^*) = x^*, \qquad f'(x^*) = -1, \qquad (4)$$

then f_2 satisfies three conditions:

$$f_2(x^*) = x^*, \qquad f_2'(x^*) = +1, \qquad f_2''(x^*) = 0. \qquad (5)$$

As a result, $x - f_2(x)$ must be approximated by a cubic near the bifurcation. One of its zeros is the (now unstable) fixed point of f , the other two constitute the period-doubled orbit, because they are not fixed points of f .

In the case of the logistic map, the first period doubling occurs at $r = 3$. Graphs of f and f_2 show the mechanism (Figure 1). As the cascade proceeds,

the pictures and the analysis repeat but with increasing complication. The common thread is that, at each step, conditions (4) for a composition f_n imply conditions (5) for f_{2n} .

PERIODIC BURSTING

Bursting systems show intervals of repetitive activity separated by intervals of relative quiescence, and have at least two different time scales; fast for the short period with spike-like oscillations that comprise the burst and slow for the longer period of the burst itself. Laboratory systems that exhibit bursting include the Belousov–Zhabotinsky reaction and neuronal systems. A simple conceptual model would be the bursting that is generated by switching between the active and inactive states, suggesting the coexistence of stable periodic and quiescent states. Bursting can be irregular, in which the periods between bursts are effectively random, or it can be strictly periodic. Some experimental bursting systems exhibit switching between different patterned periodic behaviors, suggesting two or more coexisting periodic states, and models have been shown to exhibit bi- or multi-rhythmicity. The exotic periodic dynamics of bursting systems—with patterning, multistability, and multi-rhythmicity provide a demonstrator for bifurcation and continuation algorithm packages.

A simple two-variable excitable or oscillatory system such as the FitzHugh–Nagumo equations can be driven to bursting by a slow periodic forcing term, so bursting can be viewed as the activity of a

fast oscillatory system being modulated by a slower oscillatory system. For an autonomous bursting system, the fast and slow systems are coupled, and the burst is generated by the evolution of the slow system sweeping the dynamics of the fast subsystem between steady state and oscillatory dynamics (Chay & Rinzel, 1985). On the timescale of the fast system, the slow variable acts as a control parameter, so the fast variable approximates its attractors—its stable equilibrium during the period of quiescence and its oscillations during activity.

Bursting in neurons and other electrically excitable secretory cells may be part of their normal pattern generation behavior, as in the generation of the respiratory rhythm, or a sign of pathology, as in the abnormal bursting charges during epileptic fit. Synchronization of bursting activity between widely separate cells in the cortex excited by different features of the same visual input has been observed and proposed to underlay visual binding. Neural central pattern generators are networks of nerve cells, that generate periodic bursts as a result of their interconnections, but some single isolated cells can generate bursts. Both network and isolated cell bursting can be modeled by systems of differential equations. Specific models for isolated cells—the beta-pancreatic cell or the parabolic burster cell R15 of *Aplysia*—are ordinary differential systems, analogous to the Hodgkin–Huxley equations for the action potential, based on experimental measurements of currents and concentrations (Rinzel & Lee, 1986). They reproduce the observed bursting behaviors and can be reduced to simpler systems in which the dynamical mechanisms producing bursting are obtained by bifurcation analysis of these models.

In these models, the spiking is produced by oscillations of a fast subsystem that is modulated by the slower system. Bifurcation and topological analysis of the models has led to a classification of the types of bursting (Bertram et al., 1995). In type I, the fast subsystem is bistable, and the burst begins at a saddle node and ends at a homoclinic bifurcation. During the burst, the period between spikes increases illustrated by a simple three-variable polynomial model that retains the qualitative features of neuronal bursting, the Hindmarsh–Rose equations (1984) in Figure 1. The stable (thick solid line) and unstable (dotted line) Z-shaped steady state curves exchange stability at a Hopf bifurcation and a saddle-node bifurcation, and the periodic solutions that emerge at the Hopf bifurcation end at a homoclinic point. The xy subsystem has a bistable range, with stable steady state and limit cycle. During the burst, z is approximately constrained to this bistable range, each spike increments z , and the period between spikes increases as the homoclinic point is approached. Between bursts, z decreases slowly close to the lower, stable limb of the steady-state curve, as x increases until the orbit is re-injected into the spiking region.

Figure 1. Example of type I burst generation in the three-variable (x, y, z) Hindmarsh & Rose (1984) model for neuronal oscillations, bursting and chaos. (a) Periodic bursting in the fast x variable representing membrane potential; (b) and (c) with z scale magnified: Bifurcation diagram for the fast $x-y$ subsystem with the slow variable z treated as a bifurcation parameter, and the periodic bursting of (a) is overlaid in the $x-z$ plane.

In type II bursting, two slow variables drive the fast system across a homoclinic bifurcation, so the spike period within the burst decreases and then increases parabolically, as the slow variables drive the system toward, and away from, the homoclinic point. This is illustrated by the parabolic burster R15 of Aplysia. The fast system has only a stable periodic limit cycle during the burst.

In type III bursting, as in type I, the fast system is bistable, but the burst ends at a saddle node rather than a homoclinic bifurcation, and the spike period need not increase during the burst.

Examples of all three types are seen in different bursting cells, and many bursting cells show more exotic, and chaotic, behaviors. An alternative approach is to reduce the models to interval maps, and to classify the bifurcations of these maps—see Fan & Holden (1993).

PERIODIC ORBIT THEORY

Many characteristic quantities for chaotic systems, such as Lyapunov exponents, correlation functions, or fractal dimensions, are defined as averages over the invariant measure (defined as a probability distribution on the phase space). For most chaotic systems, this measure is difficult to represent analytically, so it has to be approximated experimentally or numerically by averages over long trajectories. The periodic orbit theory rests on the idea that periodic orbits provide a skeleton that allows approximation of the invariant measure and that, therefore, ergodic averages can be determined from suitably weighted averages over periodic orbits. It combines mathematically established analytical expressions with well-controlled numerical input for highly accurate quantitative information about chaotic systems. It provides access to Lyapunov exponents, fractal dimensions, escape rates, diffusion constants, resonances, or even correlations between eigenvalues of quantum systems (Eckmann & Ruelle, 1985; Artuso et al., 1990; Chaos Focus Issue, 1992).

In order to motivate the basic expressions and to determine the weight of periodic orbits, consider the evolution of a density $\rho_n(\mathbf{x})$ at time n under the action of a discrete dynamical system, $\mathbf{x}_{n+1} = \mathbf{F}(\mathbf{x}_n)$ (Cvitanović & Eckhardt, 1991). After one time step, the density is given by

$$\rho_{n+1}(\mathbf{x}) = \int d\mathbf{y} U(\mathbf{x}, \mathbf{y}) \rho_n(\mathbf{y}) \quad (1)$$

with the evolution kernel $U(\mathbf{x}, \mathbf{y})$. In the deterministic map, the points $\mathbf{y}$ at time n and $\mathbf{x}$ at $n+1$ are connected by a single trajectory, so that U is a δ -distribution, $U = \delta(\mathbf{x} - \mathbf{F}(\mathbf{y}))$. In the presence of noise, the evolution kernel will be more regular and some of the mathematical subtleties that appear when dealing with singular operators will disappear. Noise

regularization can also be used to define the “natural” invariant measure for a dynamical system, the Sinai–Ruelle–Bowen measure, as the measure obtained in the limit of vanishing noise (Eckmann & Ruelle, 1985). For an attractor, this invariant measure is the eigenvector to the eigenvalue 1 of the evolution operator.

Periodic orbits appear when traces of U are calculated: the trace requires that $\mathbf{x}$ and $\mathbf{y}$ coincide, and this singles out a periodic orbit. With p the label for the different periodic orbits, n_p their primitive period (the number of iterations need to first return to the starting point), and $J_p = d\mathbf{x}(n_p) / d\mathbf{x}(0)$ the Jacobian after one period, the trace for m iterations becomes

$$\begin{aligned} \text{tr } U^m &= \int d\mathbf{x} U^m(\mathbf{x}, \mathbf{x}) \\ &= \sum_p \sum_{r=1}^{\infty} \frac{n_p}{|\det(1 - J_p^r)|} \delta(m - rn_p); \end{aligned} \quad (2)$$

powers of U are defined as multiple mappings so that U^m is the evolution operator after m time steps. The first sum extends over the primitive, nonrepeated orbits p and the second over their multiple traversals r .

The Fredholm determinant for the evolution operator U can be related to traces of the evolution operator via

$$\begin{aligned} \det(1 - zU) &= \exp(\text{tr} \ln(1 - zU)) \\ &= \exp\left(-\sum_{n=1}^{\infty} \frac{z^n}{n} \text{tr } U^n\right) = \sum_{l=0}^{\infty} c_l z^l. \end{aligned} \quad (3)$$

(4)

The right-hand side is then an expansion in terms of periodic orbits, first through the traces in the exponent and then through their contributions to the coefficients c_l in the final power series. The left-hand side can formally be expanded in terms of eigenvalues λ_p of the operator, $\det(1 - zU) = \prod_p (1 - z\lambda_p)$. It vanishes whenever z equals the inverse of an eigenvalue.

The formal manipulations that lead to (4) can be made precise in the context of nice hyperbolic systems in which periodic orbits are dense (“Axiom A”). Simple maps and flows on surfaces of negative curvature belong to this class. Then the theory can be developed as discussed in Ruelle (1989) and Pollicott (2002). In particular, the eigenvalues with sufficiently small damping can be given an interpretation as experimentally accessible long-lived Ruelle–Pollicott resonances.

For the calculation of averages, the relation between the leading eigenvalue and the invariant density is important. If the average of a given phase space observable A is to be calculated, one can extend the transfer operator U to include the observable, $\tilde{U} = U \exp(-qA)$, and extract the phase space average from the variation of the leading, zero $z_0(q)$ of the

Fredholm determinant with q ,

$$\langle A \rangle = \frac{d}{dq} \ln z_0(q) \Big|_{q=0}. \quad (5)$$

The contribution to the trace is a term $\exp(q \sum_p A(\mathbf{x}_p))$ with the sum extending over all points P of the orbit p : it reflects the sampling of phase space along the orbit.

The dependence of the Fredholm determinant on periodic orbits and their properties can be spelled out completely, so that it can be written as a product over contributions from periodic orbits. For the case of a one-dimensional map, we find

$$\begin{aligned} \det(1 - zU) &= \prod_p \prod_{j=0}^{\infty} \left(1 - \frac{z^{n_p}}{|J_p| J_p^j}\right) \\ &= \prod_j \zeta_j^{-1}(z). \end{aligned} \quad (6)$$

The ζ_j are called dynamical zeta functions in analogy to the Riemann zeta function $\zeta_{\mathbb{R}}(s)$, which by the Euler product representation can be expressed as a product over prime numbers,

$$\zeta_{\mathbb{R}}^{-1}(s) = \left(\sum_{n=1}^{\infty} n^{-s}\right)^{-1} = \prod_p (1 - p^{-s}). \quad (7)$$

The analytic properties of the Fredholm determinant determine the decay of the coefficients c_l in the power series expansion in (4): if the Fredholm determinant is analytic then the coefficients fall off faster than exponentially (Rugh, 1992). This is particularly useful in numerical calculations where highly accurate and quickly converging results can be obtained using the shortest orbits.

For continuous flows, the discrete period z^{n_p} is replaced by the continuous equivalent $\exp s T_p$, and the contributions of observables becomes an integral along the orbit.

When the classical evolution operator is replaced by the quantum one, a relation between the quantum eigenvalues and classical periodic orbits emerges (Gutzwiller, 1990). For instance, the semiclassical periodic orbit expression for the density of states in a chaotic system is

$$\begin{aligned} \rho(E) &= \sum_i \delta(E - E_i) \\ &\sim \text{Re} \frac{1}{\pi \hbar} \sum_p \sum_{r=1}^{\infty} \frac{T_p \exp(-i\mu_p \pi r / 2)}{\sqrt{|\det(1 - J_p^r)|}} e^{ir S_p(E)/\hbar}, \end{aligned} \quad (8)$$

where the symbol $\sim$ indicates the omission of a few regularizing terms, and where S_p and μ_p are the

classical action and the Maslov index, respectively. This Gutzwiller trace formula is at the heart of many developments in the field of quantum chaos.

Zeta functions for the counting of periodic orbits already appear in Smale (1967). The mathematical theory was developed prominently by David Ruelle, Rufus Bowen, and Yasha Sinai (see Eckmann & Ruelle, 1985; Ruelle, 1989; Pollicott, 2002). Practical aspects for calculating with periodic orbits are discussed by Artuso et al. (1990), by Gaspard (1998), and by many contributions to the Chaos Focus Issue (1992). Applications of this formalism to simple maps and the period-doubling attractor are given by Artuso et al. (1990), to diffusion in Lorentz gases in Chaos Focus Issue (1992), and to the dimension and resonances to the Lorenz model in Eckhardt & Ott (1994). The relation to quantum mechanics is discussed in Gaspard (1998), Gutzwiller (1990), Eckhardt (1993), and the Chaos Focus Issue (1992). As demonstrated by Flepp et al. (1991), a comparison between periodic orbits extracted from experimental data and from a numerical model can be used to fine tune and improve the model.

PERIODIC SPECTRAL THEORY

The direct problem of periodic spectral theory is that of constructing the spectral data of certain linear operators with periodic coefficients, that is, the determination of the spectrum of this operator and of the associated eigenfunctions. The inverse problem of periodic spectral theory is the problem of the reconstruction of such an operator (and thus its coefficients) from given spectral data. Although these questions can be asked for linear partial differential operators, this article focuses on linear ordinary differential operators.

The history of periodic spectral theory starts with the investigations of Sturm and Liouville on the eigenvalues of certain differential equations of second-order with given boundary conditions, now referred to as Sturm–Liouville theory. In 1836–1837, Charles François Sturm and Joseph Liouville examined independently different aspects of this problem, such as the asymptotics of eigenvalues, different comparison theorems on the solutions of similar equations with different coefficients, and theorems on the zeros of eigenfunctions. For the class of equations Sturm and Liouville considered, these results imply the existence of an infinite sequence of real, increasing eigenvalues, and orthogonality of eigenfunctions corresponding to different eigenvalues. Although their investigations did not as such deal with periodic spectral theory, many of their results carry over to this area.

Consider an ordinary differential operator of order n ,

$$L = q_n(x) \frac{d^n}{dx^n} + q_{n-2}(x) \frac{d^{n-2}}{dx^{n-2}} + \cdots + q_1(x) \frac{d}{dx} + q_0(x), \quad (1)$$

where the coefficients $q_j(x)$, $j=0, \dots, n$ are periodic functions of x , sharing a common period: $q_j(x+T) = q_j(x)$, $j=0, \dots, n$, and $q_{n-1}(x) = 0$. They are referred to as potentials. Using this operator L , define the differential equation

$$L\psi = \lambda\psi. \quad (2)$$

The direct periodic spectral problem is the problem of (i) determining the set of all $\lambda \in \mathbb{C}$ for which this differential equation has at least one bounded solution, and (ii) for each such λ , determining all bounded solutions. There are many technical issues to be dealt with: which function space do the potentials belong to? Which function space does ψ belong to? These issues will be ignored here. Sometimes one restricts attention to periodic solutions $\psi: \psi(x+T) = \psi(x)$, or antiperiodic solutions $\psi(x+T) = -\psi(x)$. These and other choices lead to spectra that are subsets of the spectrum as obtained without making these choices.

One approach to solve the direct spectral problem is Floquet theory (Amann, 1990). Rewrite Equation (2) as

a first-order linear system:

$$\frac{d\psi}{dx} = X(x, \lambda)\psi, \quad X(x+T, \lambda) = X(x, \lambda) \quad (3)$$

with $\psi_1 = \psi(x)$. Note that from $q_{n-1}(x) = 0$, it follows that $\text{tr } X(x, \lambda) = 0$. Thus, the flow determined by (3) is volume preserving. Define the monodromy matrix of this system as $M(x_0, \lambda) = \Psi(x_0 + T, x_0, \lambda)$, where $\Psi(x, x_0, \lambda)$ is a fundamental matrix of (3) such that $\Psi(x_0, x_0, \lambda)$ is the identity matrix. Thus, $M(x_0, \lambda)$ is the operator of translating x by T : $M(x_0, \lambda)\psi(x) = \psi(x + T)$. Note that $\psi(x)$ also depends on x_0 and λ , but this dependence is suppressed here. This operation commutes with d/dx , since $X(x, \lambda)$ is periodic in x with period T . Thus, (3) has a set of solutions $\phi(x)$ which are also eigenvectors of $M(x_0, \lambda)$. These solutions are known as Bloch functions or Floquet functions. If the eigenvalue of $M(x_0, \lambda)$ for any Bloch function has magnitude greater than one, then this Bloch function is unbounded as $x \rightarrow +\infty$ or $x \rightarrow -\infty$. Thus, the spectrum of (3) is the set of all λ such that at least one eigenvalue of $M(x_0, \lambda)$ has magnitude one. This spectrum is independent of the choice of x_0 due to the requirement that the flow is volume preserving; that is, $\text{tr } X(x, \lambda) = 0$, or $q_{n-1}(x) = 0$.

An important class of periodic spectral problems is that of self-adjoint operators. These are operators whose spectrum is contained on the real line. For self-adjoint operators, the spectrum of the periodic spectral problem consists of the union of a (possibly infinite) sequence of intervals.

For the sake of explicitness, the remainder of this article will discuss the equation (Magnus & Winkler, 1979)

$$-\psi'' + q(x)\psi = \lambda\psi, \quad q(x+T) = q(x). \quad (4)$$

Note that many of the results stated below are true for general classes of periodic spectral problems. Depending on the literature source, (4) goes by the name of Hill's equation or (after rescaling) the time-independent Schrödinger equation. This equation is self-adjoint. Its spectrum is bounded from below. It is a collection of intervals such that the length of the separating gaps between intervals $\rightarrow 0$ as $\lambda \rightarrow \infty$. Using Floquet theory, the condition for λ to be in the spectrum is found to be $|\text{tr } M(x_0, \lambda)| \leq 2$. The endpoints of the intervals are given by $|\text{tr } M(x_0, \lambda)| = 2$. Because (4) is a second-order equation, there are two linearly independent Bloch functions.

The time-independent Schrödinger equation (4) of course plays a fundamental role in quantum mechanics. In this case, $q(x)$ is the potential of the system, and λ plays the role of energy. The context of solid state physics is especially relevant here, because the potential $q(x)$ is periodic. The intervals constituting the spectrum are known as allowed (energy) bands and the gaps between them as forbidden (energy) bands.

The inverse periodic spectral problem for (4) is that of the reconstruction of $q(x)$, given a collection of spectral data. Various choices are possible for the collection of spectral data. In general, the inverse problem does not have a unique solution, using the knowledge of one spectrum. This can be resolved by also providing the eigenfunction. However, now the collection of spectral data is unnecessarily large. It is sufficient to provide two spectra (corresponding to different boundary conditions). Together with the known analyticity properties of the eigenfunction $\psi(x)$, this determines the potential $q(x)$. This is similar to the inverse scattering method where the knowledge of the scattering data and the analyticity properties of the eigenfunction determine the potential (decaying as $|x| \rightarrow \infty$) uniquely. A major difference is that in the inverse scattering method, the starting point is the asymptotic behavior as $x \rightarrow \pm\infty$. This behavior is simple, because it is governed by a differential equation with constant coefficients. This is one reason why the inverse scattering method is as efficient as it is. In the periodic problem, the role of $x \rightarrow \pm\infty$ is taken over by $x = x_0$, but there is no simple asymptotic behavior, resulting in a theory which is more technical and less explicit (Dubrovnik et al., 1976; Novikov et al., 1984).

This lack of explicitness for solving the inverse periodic spectral problem is to some extent resolved by the consideration of so-called finite-gap potentials. These are potentials for which the number of intervals constituting the spectrum, and thus, the number of gaps separating these intervals, is finite. The simplest nontrivial example is that of the Lamé equation

$$-\psi'' + n(n+1)\wp(x - x_c)\psi = \lambda\psi. \quad (5)$$

Here $\wp(x - x_c)$ is the Weierstrass elliptic function, x_c is a fixed complex number, and n is a positive integer. In this case, the number of gaps separating the intervals in the spectrum is n .

This classical example is a special case of a more recent theory of finite-gap potentials, whose development started with the works of Novikov (1974) and Lax (1975). They show that the stationary solutions of the n th member of the KdV hierarchy are n -gap potentials of (4). Here the KdV hierarchy is the collection of equations of the form $u_t = \partial_x(\delta H_n / \delta u)$, where H_n is any conserved quantity of the KdV equation, $\delta H_n / \delta u$ denotes the variational derivative of H_n with respect to u (See **Poisson brackets**), and indices denote differentiation. It was soon thereafter shown that all finite-gap potentials of (4) were of this nature. For example, the Lamé potential with $n=1$ is a stationary solution of the KdV equation. This gives a nonspectral characterization of the finite-gap potentials.

To solve the direct spectral problem with an n -gap potential $q_n(x)$, one first considers the direct periodic spectral problem, as stated above. It is solved using

Figure 1. The main spectrum for a three-gap potential (thick solid line) and the auxiliary spectrum μ_1, μ_2 and μ_3 .

Floquet theory. The outcome is the main spectrum, consisting of n finite intervals and one infinite interval. The endpoints of these intervals are labeled λ_1, λ_2 , etc., in increasing order, as shown in Figure 1. At the endpoints, only one of the eigenfunctions is bounded. These eigenfunctions are periodic with period T or $2T$. There are an infinite number of isolated eigenvalues inside the interval of infinite length for which there are two bounded, periodic eigenfunctions. Next, one considers the Dirichlet problem

$$\begin{cases} -\psi'' + q_n(x)\psi = \lambda\psi, \\ \psi(x_0) = 0, \quad \psi(x_0 + T) = 0. \end{cases} \quad (6)$$

The spectrum of this problem is referred to as the auxiliary spectrum. It is discrete, and its points $\mu_k(x_0)$, $k = 1, 2, \dots$ depend on x_0 . All but n of its points lie inside the infinite interval of the main spectrum. Each remaining point lies in a different gap of the main spectrum. This is illustrated in Figure 1. The information contained in the main and auxiliary spectra determines the eigenfunction $\psi(x)$: it is a meromorphic function in the finite λ plane with zeros at $\lambda = \mu_k(x_0)$ and poles at $\lambda = \mu_k(x) = \mu_k(x_0)|_{x_0=x}$ (Dubrovín et al., 1976; Novikov et al., 1984).

Using the main and auxiliary spectra, the inverse periodic spectral problem is solved by (Novikov et al., 1984)

$$q_n(x) = \sum_{j=1}^{2n+1} \lambda_j - 2 \sum_{j=1}^n \mu_j(x). \quad (7)$$

This is the first of the so-called trace formulae. Other trace formulae give relationships between the potential $q_n(x)$ and its derivatives and the main and auxiliary spectra.

The proposed solution of the inverse periodic spectral problem for finite-gap potentials is not effective. It requires the solution of the direct spectral problem for all x_0 in a period of the potential in order to obtain the auxiliary spectrum as a function of x_0 . It is possible to avoid this by determining $\mu_k(x_0)$, $k = 1, \dots, n$ as a solution of a set of differential equations (Novikov et al., 1984)

$$\frac{d\mu_j}{dx_0} = \frac{\pm 2i\sqrt{\prod_{k=1}^{2n+1}(\mu_j - \lambda_k)}}{\prod_{k \neq j}^n(\mu_j - \mu_k)}, \quad j = 1, \dots, n. \quad (8)$$

The choice of sign gives the direction in which $\mu_j(x_0)$ is going in between its two endpoints.

Another approach, which solves system (8), is the use of abelian functions and Riemann surfaces

(Dubrovín, 1981; Belokolos, et al., 1994). An abelian function of n variables is a $2n$ -periodic function. As such, abelian functions generalize elliptic functions to more than one variable. All abelian functions are expressible as ratios of homogeneous polynomials of Riemann's theta function. All finite-gap potentials of (4) are abelian functions. For example, the Lamé potentials in (5) are elliptic functions, which are special cases of abelian functions.

In the context of this method, the Bloch function $\phi(x) = \phi_1(x)$ is often referred to as the Baker–Akhiezer function. One of the major results of the theory is the realization that the two Bloch or Baker–Akhiezer functions, regarded as a function of arbitrary complex λ , are distinct branches of one single-valued Baker–Akhiezer function, defined on a two-sheeted Riemann surface covering the complex λ plane (Krichever, 1989). This Riemann surface is already apparent in (8). It is

$$\eta^2 = \prod_{k=1}^{2n+1} (\lambda - \lambda_k), \quad (9)$$

which defines η as a double-valued function of λ . This surface has genus n . It is obtained from Figure 1 by choosing the intervals of the main spectrum as branch cuts and gluing the two resulting sheets together along these cuts. This Riemann surface defines a theta function $\theta(z_1, \dots, z_n | \mathbf{B})$ through its normalized period (or Riemann) matrix $\mathbf{B}$. In terms of this theta function

$$q_n(x) = c - 2 \frac{d^2}{dx^2} \ln \theta(k_1 x + \varphi_1, \dots, k_n x + \varphi_n | \mathbf{B}). \quad (10)$$

The wave numbers $k_1, \dots, k_n$ are determined as integrals of certain differentials on the Riemann surface (9) with a pole singularity at $\lambda = \infty$. The phase constants $\varphi_1, \dots, \varphi_n$ are determined by the Riemann constants on (9) and the Abel transform. The constant c is determined by a differential on (9) with a double pole singularity at $\lambda = \infty$. Thus, (10) gives an explicit form for all finite-gap potentials of (4), providing a complete solution of the inverse periodic spectral problem.

Some remarks:

(i) The emphasis on finite-gap potentials is justified in the sense that any T -periodic function is approximated arbitrarily well by an infinite sequence of finite-gap potentials with period T and increasing number of gaps (Dubrovín, 1981).

(ii) The periodic spectral problem (4) is the first half of the Lax pair for the Korteweg–de Vries (KdV) equation. As such, it allows the solution of the KdV equation with periodic initial data. The full solution of this problem requires the solution of both the direct and the inverse periodic spectral problems. The schematics is identical to that of the inverse scattering method. First, the initial condition $u(x, t = 0) = U(x)$ is used

as a potential in (4) to solve the direct periodic spectral problem. This results in the main and auxiliary spectra. The time evolution of these spectra is implied from the second half of the Lax pair: the main spectrum is independent of time, whereas the auxiliary spectrum evolves according to differential equations similar to (8). The spectral data for any time is used to solve the inverse periodic spectral problem of (4). This gives the solution $u(x, t)$ of the KdV equation such that $u(x, t)|_{t=0} = U(x)$ (Novikov et al., 1984).

(iii) The spectral theory for the time-dependent Schrödinger equation is intimately connected to the initial-value problem for the Kadomtsev–Petviashvili equation. A solution of the inverse periodic spectral problem using Riemann's theta function and Riemann surfaces also exists here. However, here there are no restrictions on the form of Riemann surfaces that appear: all compact, connected Riemann surfaces arise. Hence, the periodic spectral theory of the time-dependent Schrödinger equation has important consequences for the theory of Riemann surfaces. It has provided, for instance, a solution to the Schottky problem, which was posed in 1903 (Novikov et al., 1984; Dubrovin, 1981).

(iv) The equation

$$\frac{d^2 y}{dx^2} + (a - 2k \cos(2x))y = 0 \quad (11)$$

is Mathieu's equation. It arises from the three-dimensional Helmholtz equation by separation of variables using elliptical coordinates. It is a special case of (4), using a trigonometric potential. One is only interested in period solutions, resulting in a discrete subset of the main spectrum. The periodic solutions of this equation are referred to as Mathieu functions.

PERTURBATION THEORY

A limited number of nonlinear partial differential equations (PDEs) can be solved analytically for arbitrary initial conditions. Specific applications often lead to nonlinear PDEs that do not fall into the category that can be solved by means of the inverse scattering theory, Bäcklund transformations, or Hirota's bilinear method (Dodd et al., 1984). Examples of such PDEs with physical relevance include soliton equations with added perturbative terms describing energy gain and losses, where the original unperturbed problem is energy-conserving and hence Hamiltonian. Other problems involve nonconservative PDEs, such as nerve fibers and other reaction-diffusion type equations in general. In fluid mechanics, boundary layers possess a special challenge with singular perturbations requiring matching solutions close to a boundary and solutions far from a boundary layer. Perturbations can be additive or parametric (multiplicative), and they can be localized, periodic, quasi-periodic, or random, depending on the nature of the problem to be solved. In the case of a PDE that cannot be solved analytically, we resort to approximate analytical solutions or direct numerical analysis. The approximate solutions can be determined by various perturbation techniques. For soliton equations one procedure is to calculate the variation of the spectral data in the inverse scattering method due to external perturbations (Karpman, 1979; Kivshar, & Malomed, 1989). Another method introduces slow variation of the parameters entering the soliton solution. Variants of the latter idea include multiple scales, energy methods, and the Lindstedt–Poincaré technique. Here we shall illustrate the multiscale method applied to a perturbed nonlinear Schrödinger (NLS) equation. The method follows the ideas in Kaup (1990) with an extension presented in Nguyen et al. (1995). A general perturbed NLS equation is

$$i \frac{\partial u}{\partial t} + \frac{\partial^2 u}{\partial x^2} + 2|u|^2 u = \varepsilon R(t, u). \quad (1)$$

The complex function $u = u(x, t)$ depends on the spatial coordinate x and time t . The absolute value of the perturbation parameter ε is assumed to be much smaller than unity, and we expect that the perturbation εR on the right-hand side only slightly modifies soliton solutions of the pure NLS equation. We introduce multiple scales of the time variable according to

$$T_0 = t, \quad T_1 = \varepsilon t. \quad (2)$$

In the simplest case, we treat the single soliton solution and invoke the solution ansatz

$$u = q \exp(i\xi(\Theta - \Theta_0) + i(\sigma - \sigma_0)), \quad (3)$$

$$q = \eta \operatorname{sech}(\eta(\Theta - \Theta_0)),$$

$$\text{where } \Theta = x - 2X(T_0, T_1). \quad (4)$$

The functions X and σ are defined by $\partial X / \partial T_0 = -2\xi(T_1)$ and $\sigma = (\eta^2(T_1) + \xi^2(T_1))T_0$. To proceed, we expand q according to $q = q_0 + \varepsilon(\phi + i\psi)$ and insert into Equation (1), finding

$$Lq_0 = (\partial_{\Theta\Theta} + 2q_0^2 - \eta^2)q_0 = 0, \quad (5)$$

$$M\phi = (\partial_{\Theta\Theta} + 6q_0^2 - \eta^2)\phi = \operatorname{Re}[F], \quad (6)$$

$$L\psi = (\partial_{\Theta\Theta} + 2q_0^2 - \eta^2)\psi = \operatorname{Im}[F]. \quad (7)$$

Here, q_0 is assumed to be real, and F is a lengthy complex expression, omitted for brevity. $\operatorname{Re}[F]$ and $\operatorname{Im}[F]$ denote the real and imaginary parts of F , respectively. First a solution for q_0 is obtained and the next step is to solve the inhomogeneous Equations (6) and (7). In solving these, we shall invoke Fredholm's solvability condition, which states that the null spaces of the operators M and L are orthogonal to the right-hand sides $\operatorname{Re}[F]$ and $\operatorname{Im}[F]$, respectively. The null space of an operator L is the space spanned by the solutions of $L^\dagger z(\Theta) = 0$, where $L^\dagger$ is the adjoint operator of L . This condition guarantees a solution without secular terms and provides evolution equations for the slowly varying parameters of the form

$$\eta \frac{\partial \xi}{\partial T_1} = \int_{-\infty}^{\infty} \operatorname{Re}[R] \frac{\partial q_0}{\partial \Theta} d\Theta, \quad (8)$$

$$\frac{\partial \eta}{\partial T_1} = \int_{-\infty}^{\infty} \operatorname{Im}[R] q_0 d\Theta. \quad (9)$$

For a given perturbation R , we can solve these equations for the slowly varying soliton amplitude η and ξ .

In the previous discussion, we began with a soliton as the zero-order approximation and adjusted its parameters to achieve an approximate solution of the perturbed soliton equation. In nonlinear diffusion equations, solutions emerge from balancing sources of energy with diffusion and dissipative effects. The perturbation theory outlined above can also be applied to such systems. As an example let us consider

the FitzHugh–Nagumo (FN) model for nerve pulse propagation (FitzHugh, 1961):

$$\frac{\partial^2 V}{\partial x^2} - \frac{\partial V}{\partial t} = F(V) + R, \quad (10)$$

$$\frac{\partial R}{\partial t} = \varepsilon V, \quad (11)$$

where $F(V)$ is the cubic-shaped function $V(V - a)(V - 1)$. $V = V(x, t)$ is the voltage across the nerve cell membrane, and R is a recovery variable. The nerve pulse solution is localized in space and propagates by a velocity v to be determined from the model equations. Instead of using a multiscale approach, we invoke the Lindsted–Poincaré technique (Nayfeh, 1973) and expand the velocity parameter according to

$$v = v_0 + \varepsilon v_1 + O(\varepsilon^2). \quad (12)$$

The reason for introducing the above expansion is that nonlinearity will alter the propagation velocity. We also expand the dependent functions V and R

$$V = V_0 + \varepsilon V_1 + O(\varepsilon^2), \quad (13)$$

$$R = R_0 + \varepsilon R_1 + O(\varepsilon^2). \quad (14)$$

It is important to note that terms increasing to infinity for large times t , that is, secular terms in V_1 and R_1 , are avoided by using the expansion of the velocity in Equation (12). Introducing a traveling wave assumption $\xi = x - vt$ in the solution and substituting expressions (12)–(14) into the FN equations (10) and (11) and ordering terms in power of ε leads to

$$\frac{d^2 V_0}{d\xi^2} + v_0 \frac{dV_0}{d\xi} - [F(V_0) - R_0] = 0, \quad (15)$$

$$\frac{dR_0}{d\xi} = 0. \quad (16)$$

To order $O(\varepsilon)$ we have

$$LV_1 = \frac{d^2 V_1}{d\xi^2} + v_0 \frac{dV_1}{d\xi} - F'(V_0)V_1 = R_1 - v_1 \frac{dV_0}{d\xi}, \quad (17)$$

$$\frac{dR_1}{d\xi} = -\frac{V_0}{v_0}. \quad (18)$$

Here it turns out that we can identify “boundary layers” for the determination of V and R together with appropriate matching. In the limit of $\varepsilon \rightarrow 0$, the nerve pulse voltage rises sharply from zero to a plateau value of order $O(1)$. The rapid change is equivalent to a boundary layer in fluid dynamics. Similarly a sharp decrease of the pulse appears at its rear end followed by a slow recovery interval due to a fading R . Matching of the solutions can be done in each region. The correction term v_1 in the expansion of the velocity is determined from Fredholm's solvability condition of

Equation (17). That is, the null space of the operator L should be orthogonal to the right-hand side of (17). This is equivalent to the requirement for the NLS equation in the previous section. For $a < \frac{1}{2}$ the traveling wave velocity v_0 of the leading edge is $v_0 = (1 - 2a) / \sqrt{2}$ and the first-order correction becomes

$$v_1 = \frac{\int_{-\infty}^{\infty} \left[\int_{\xi}^{\infty} V_0(\xi') d\xi' \right] (dV_0/d\xi) e^{v_0 \xi} d\xi}{v_0 \int_{-\infty}^{\infty} (dV_0/d\xi) e^{v_0 \xi} d\xi}. \quad (19)$$

As we have used a traveling wave ansatz, the obtained solution for V_0 may not be stable. However, a closer analysis reveals that stable traveling wave solutions exist (Scott, 2003). Random perturbations make up a set of conceptually different problems that may be treated by methods of stochastic differential equations and statistics. For soliton equations, studies have been performed on random parameters modeling the stochastic variation of various physical properties, such as geometry or material. The influence of thermal noise and incoherence of amplitude and phase modulations of input pulses are other important examples (Abdullaev, 1994; Abdullaev et al., 2001).

PHASE DYNAMICS

Phase as a physical term is most commonly used in reference to oscillatory processes. The concept of phase dynamics is particularly relevant to self-sustained or

limit-cycle oscillations. The orbital shape of a limit cycle is more or less rigid against perturbations, while the remaining degree of freedom along the closed orbit (the phase) lacks such rigidity. Consequently, when a limit-cycle oscillator is slightly perturbed, the resulting nontrivial dynamics could well be described in terms of the phase alone. This is the intuition behind the phase description of a variety of oscillatory phenomena, among others biological oscillations (Winfree, 2000).

Mathematically, limit-cycle oscillations are described with a time-periodic solution of an autonomous nonlinear ordinary differential equation $dX/dt = F(X)$, $X \in R^n$. Let such a solution with angular frequency ω be given by a 2π -periodic function $X_0(\omega t + \phi_0)$ involving an arbitrary phase constant ϕ_0 . One may also introduce a phase variable $\phi(t)$ to represent this one-parameter family of solutions as

$$X(t) = X_0(\phi(t)), \quad \frac{d\phi}{dt} = \omega. \quad (1)$$

Suppose the oscillator is slightly perturbed, by which F is slightly modified. As the resulting deformation of the closed orbit would be negligibly small, the first equation in (1) still holds approximately, while the correction to the instantaneous frequency $d\phi/dt$, however small it may be, would give rise to a large difference in ϕ in the long run and hence is indispensable.

Further, suppose that the perturbation represents the influence from another oscillator with state vector X' coupled weakly to the first one. If these oscillators are identical in nature, one may also use the approximation $X'(t) = X_0(\phi'(t))$ for the second oscillator, so that the current state of our oscillator pair may well be specified only with their phases $\phi(t)$ and $\phi'(t)$. Therefore, the small term to be added to the phase equation in (1) should generally be given by some function $G(\phi, \phi')$ which is 2π -periodic both in ϕ and ϕ' . Due to the assumed smallness of G relative to ω , it turns out that the effect of G over one cycle of oscillation depends only on the phase difference $\phi - \phi'$. Thus, using a 2π -periodic function Γ , one may obtain

$$\frac{d\phi}{dt} = \omega + \Gamma(\phi - \phi') \quad (2)$$

and, if we need, a similar equation for the second oscillator also. The function Γ can be computed in principle with the knowledge of the original dynamical-system model. Note, however, that the formula for Γ requires an extension of the definition of phase slightly outside the limit-cycle orbit (Kuramoto, 1984a).

The above equation may readily be extended to larger assemblies of weakly coupled oscillators. Furthermore, the oscillators may be slightly dissimilar, with their effect appearing only through a small difference in natural frequency ω . Thus, for such an

assembly of N oscillators, we generally have

$$\frac{d\phi}{dt} = \omega_i + \sum_{j=1}^N \Gamma_{ij}(\phi_i - \phi_j), \quad i = 1, 2, \dots, N. \quad (3)$$

This is called the phase oscillator model which is extremely useful for the study of complex collective behavior of large assemblies of coupled oscillators appearing in large varieties of fields ranging from physics to brain science (Pikovsky et al., 2001).

Phase dynamics are also useful when the oscillators constitute a continuous field. As a representative class of such continua, we will focus on oscillatory reaction-diffusion systems given by

$$\frac{\partial X}{\partial t} = F(X) + \hat{D} \nabla^2 X, \quad (4)$$

where $X(r, t)$ represents a space-time-dependent composition vector of dimension n and $\hat{D}$ is a diagonal matrix of n diffusion constants. If the spatial variation of X is of long wavelength, the diffusion term can be regarded as a small perturbation driving each local oscillator, so that the previous idea of phase dynamics should work. The approximation $X(r, t) = X_0(\phi(r, t))$ would again be valid at each spatial point. Its application to the diffusion term produces terms proportional to $\nabla^2 \phi$ and $(\nabla \phi)^2$. According to a systematic perturbation theory, such terms actually appear in the phase equation. Specifically, we obtain a nonlinear phase diffusion equation

$$\frac{\partial \phi}{\partial t} = \omega + \nu \nabla^2 \phi + \mu (\nabla \phi)^2 \quad (5)$$

to the nontrivial lowest order approximation with respect to the smallness in the spatial gradient of ϕ , where positive ν has been assumed. If ν is negative, the uniform oscillation is unstable. For small negative ν , the idea of phase dynamics still works. Then (5) is modified to give an equation equivalent to the Kuramoto-Sivashinsky equation, whose solution describes spatiotemporal chaos called phase turbulence.

In a more general context, phase is a degree of freedom appearing when a certain continuous symmetry of the system has been broken spontaneously (Mori & Kuramoto, 1998). For instance, the phase of a limit-cycle oscillator reflects the fact that the oscillation breaks the invariance of the governing evolution equation (assumed autonomous) with respect to temporal translations $t \rightarrow t + t_0$. Such symmetry-breaking solutions, not restricted to time-periodic solutions, generally involve an arbitrary phase constant, thus forming an infinite family recovering as a whole the original symmetry. This also means that phase has no prescribed value to which it is bound to relax or, equivalently, phase represents a neutrally

stable dynamical variable. When the system is weakly perturbed, such neutrality is slightly violated causing the phase to evolve slowly, possibly apart from a constant drift. In contrast, all the other degrees of freedom will damp quickly, thus following adiabatically the slow motion of the phase. This explains why the phase so often dominates the pattern dynamics in nonlinear dissipative systems.

The general argument given above implies that the applicability of phase dynamics is by no means restricted to oscillatory systems. Two important non-oscillatory applications of phase dynamics, again in reference to reaction-diffusion systems with large spatial extension, will be touched upon next.

Reaction-diffusion systems may develop a spatially periodic static pattern out of a uniform state through the Turing instability, by which the spatial translational symmetry has been broken. When the local phase of the periodic pattern is subject to a large-scale spatial modulation, phase dynamics is applicable and describes the pattern dynamics through a slow evolution of the phase (Kuramoto, 1984b). For instance, the transient dynamics of recovery of a regular pattern can be described with a simple phase-diffusion equation.

Another important class of symmetry-breaking patterns arising in reaction-diffusion systems is localized structures such as moving domain boundaries and solitary pulses. In these cases, phase corresponds to the location of a moving front. For a planar front, the phase forms a uniform field advancing at a constant speed. When the planar front is deformed slightly in large spatial scale, the phase becomes slightly non-uniform and starts to evolve slowly. It is concluded from a systematic theory of phase dynamics that when the planar front is stable, the equation for the phase takes the same form as (5) with ∇ being replaced with a gradient of reduced dimension (Kuramoto, 1984a). A planar front that is weakly unstable due to small negative ν leads to phase turbulence described essentially by the Kuramoto-Sivashinsky equation.

PHASE PLANE

The term *phase plane*, naturally enough, refers to the phase space of a two-dimensional dynamical system. The term is worthy of consideration in its own right because of the various special techniques that exist for the analysis of two-dimensional continuous-time dynamical systems (i.e., flows).

As an example, consider the two-dimensional flow induced by the following differential equations:

$$\begin{aligned}\dot{x}_1 &= x_1(1 - x_2), \\ \dot{x}_2 &= x_2(x_1 - r).\end{aligned}\quad (1)$$

Each of these equations specifies one component of a two-dimensional vectorfield on the plane, tangent at each point to the induced flow. Equations (1) were first employed by Alfred Lotka (1920) to describe a hypothetical bimolecular chemical reaction capable of sustained oscillations, assuming mass action kinetics. At about the same time and independently, Vito Volterra (1926) made use of the same equations to model the interaction of biological predator and prey populations. In Equations (1), x_1 denotes the density of the prey species and x_2 that of the predator. Figure 1a shows the relevant (positive) quadrant of the phase plane of Equations (1).

The most important aspects of the dynamics of smooth flows are determined by their α - and ω -limit sets. The former are those sets approached by an orbit as $t \rightarrow -\infty$; the latter, those approached as $t \rightarrow +\infty$. In smooth planar flows, these limit sets are of only three types: singular points (or equilibria), closed (or periodic) orbits, and homo- and heteroclinic chains. The last are made up of singular points together with bounded orbits, each of which has one singular point as α -limit and another (possibly identical) singular point as ω -limit. It should be noted that more complex behaviors such as quasi-periodicity and chaotic dynamics are not possible in two-dimensional flows.

Singular points are determined as the solutions of a system of two algebraic equations and classified, on the basis of linear stability analysis, into six types: stable and unstable nodes, stable and unstable foci, centers, and saddles. Useful information about the simultaneous existence of singular points and closed orbits can be obtained from consideration of the Poincaré index, an integer associated with each singular point (See **Winding numbers** and Andronov et al., 1966). For example, the Poincaré index can be used to show

Figure 1. (a) Phase plane of the Lotka–Volterra equations (1). Representative orbits are shown as solid lines; the direction of flow is indicated by arrows. The isoclines are shown using dashed lines. The positive quadrant is filled with a family of closed orbits, corresponding to the fact that equations (1) are Hamiltonian. (b) Diagram showing a generic isocline analysis: many qualitative features of the dynamics are made plain. The isoclines show the loci where the vectorfield is horizontal or vertical. Intersections of the isoclines occur at singular points. From left to right, the three singular points are evidently of focus, saddle, and stable node types. It is not clear from the isocline analysis alone whether the focus is stable or unstable.

that every closed orbit encircles at least one singular point.

The method of isoclines is frequently invaluable in deriving qualitative information about the dynamics of a given smooth flow. An isocline is the locus where one of the vector field components vanishes. The two isoclines together split the phase plane into four divisions: within each such division each vector field component has a uniform sign. Figure 1b depicts a typical isocline analysis.

Closed orbits which attract or repel nearby orbits are called limit cycles. Systems possessing stable limit cycles are said to exhibit auto-oscillations. The method of Liénard can be used to demonstrate the existence of limit cycles in certain systems (Hartman, 2002). Sometimes, a limit cycle can also be found

Figure 2. Determining a heteroclinic connection by shooting. Adjusting a parameter (in this case the wave speed c) causes the unstable manifold of the rightmost saddle point to move. For small positive values of c , one branch of the unstable manifold crosses the negative v -axis, never to return (a). At larger values of c , it is drawn into the stable focus point at $u = a$, $v = 0$ (c). There is precisely one intermediate value $c = c^*$ for which a branch of the unstable manifold of the rightmost saddle coincides with a branch of the stable manifold of the leftmost saddle, i.e., for which there is a heteroclinic connection (the emboldened orbit in b).

by association with a Hopf bifurcation (Arnol'd, 1973; Hale & Koçak, 1991). The Poincaré–Bendixson theorem can also be used to demonstrate the existence of limit cycles. It states that any non-empty compact α - or ω -limit set of a smooth planar flow which does not contain a singular point is a closed orbit.

Homo- and heteroclinic chains are, in general, more difficult to determine than equilibria. So-called shooting methods may sometimes be used to prove the existence of homoclinic or heteroclinic connections. For example, consider the following planar system, which arises as the traveling wave reduction of the Zeldovich–Frank–Kamenetsky equation

$$\begin{aligned}\dot{u} &= v, \\ \dot{v} &= u(u-a)(u-1) - cv.\end{aligned}\quad (2)$$

Here, the parameter c is a wave speed (See **Wave of translation**), and we assume (without loss of generality) that $0 < a < \frac{1}{2}$. It is readily seen that there are precisely three singular points (at $u=0$, a , 1 and $v=0$); the first and third are saddles; the intermediate is of focal type (see Figure 2). If we seek a rightward moving wave ($c > 0$), this focus is stable. For small values of c , the lower branch of the rightmost saddle's unstable manifold crosses the negative v -axis, where as for sufficiently large values of c , it crosses the positive u -axis before winding about the stable focus. It follows that there is an intermediate wave speed c^* for which a heteroclinic connection exists. It should be noted that this shooting argument depends on the fact that deleting a point from an interval in two-dimensional space topologically disconnects the interval. Shooting methods become more complicated in higher dimensions (see, e.g., Dunbar, 1984).

PHASE SPACE

The equations of motion of a mechanical system are usually of second order, and they determine the entire future from the initial *state*, which consists of both positions and velocities. The space of all states is called the *phase space*. For the mathematical pendulum (a point mass in the plane at one end of a massless rod whose other end is fixed), the configuration space is a circle, at each point of which one can choose any tangent vector as the velocity. Therefore, the phase space is a circle with a line attached to each point, that is, a cylinder. The pendulum equation for the position x and velocity v , $\ddot{x} + \sin x = 0$ converts to $(\dot{x}, \dot{v}) = (v, -\sin x)$, so the dynamics is described by integral curves of the vector field $R(x, v) = (v, -\sin x)$ on the cylinder.

That the notion of phase space is natural is also suggested by the Liouville theorem: the skew-symmetry of the Hamilton equation makes the Hamiltonian vector field divergence-free, and accordingly, a Hamiltonian flow preserves the volume on phase space.

Generally, a dynamical system consists of a phase space and a time-evolution of first order. The phase space is a set with some structure, such as differentiable (in the case of differential equations, this belongs to smooth dynamics), topological (one then speaks of topological dynamics), or measurable (this is the subject of ergodic theory, which arose from the Liouville theorem), and the time evolution is a one-parameter family of transformations that preserve this structure and that map initial states to states at another time. The time parameter may run through real numbers (continuous-time system) or integers (discrete-time system, iterations of a map and possibly its inverse). Specifically, a continuous-time system is given by a family $(f^t)_{t \in \mathbb{R}}$ of maps. If $f^t(f^s(x)) = f^{t+s}(x)$ for every s, t, x , then we say that this family is a flow. In the discrete-time case, one considers the iterates $(f^n)_{n \in \mathbb{Z}}$, where $f^0(x) = x$, $f^{n+1}(x) = f(f^n(x))$ for $n \geq 0$, and $f^n(x) = (f^{-1})^n(x)$ for $n < 0$, or if the map is not invertible, only positive iterates $(f^n)_{n \in \mathbb{N}}$. The maps $f_a(x) = ax(1-x)$ are a popular example of the latter (the so-called logistic map).

The long-term behavior of flows in the plane is well understood (See **Phase plane**): In the long run, any orbit either approaches fixed points

or is asymptotically periodic (Poincaré-Bendixson theorem). This is ultimately due to the fact that a closed curve, such as a periodic orbit, divides the plane into separate regions. Already in three-space, one gets chaotic behavior, such as in the Lorenz attractor.

Qualitative Theory of Differential Equations and Dynamical Systems

On the phase space of a smooth continuous-time dynamical system, the time evolution is given by a first-order differential equation $\dot{x} = R(x, t)$. Suppose the right-hand side R satisfies a Lipschitz condition in x . This means that there is a constant M such that $d(R(x, t), R(x', t)) \leq Md(x, x')$ for all x, x' . The basic Picard theorem then guarantees existence and uniqueness of solutions for any initial condition. Otherwise solutions may not be unique ($\dot{x} = \sqrt[3]{x}$ has infinitely many solutions with initial value 0) or may not exist for any uniform amount of time (the solutions of $\dot{x} = x^2$ have singularities).

If solutions $x(t)$ exist for all time, as we henceforth assume, they define time- t -maps by $f^t(x(0)) = x(t)$. Each map f^t is as smooth as the right-hand side R of the differential equation (smooth dependence on initial conditions).

If R is independent of t , then the differential equation is said to be “autonomous,” and R gives a vector field on the phase space that prescribes the velocity vectors of solutions. The family of time- t -maps is then a flow. The iterates of the time-1-map of a flow produce a discrete-time dynamical system whose study may yield useful information about the flow. If R depends on t , the system is said to be non-autonomous. Explicit time dependence can, for example, arise from forcing terms (forced pendulum $\ddot{x} + \sin x = \sin \omega t$) or from varying parameters (driving of a swing by parametric forcing, $\ddot{x} + \rho(t) \sin x = 0$).

An “orbit” or *trajectory* of a continuous-time system is a parametrized curve $(f^t(x))_{t \in \mathbb{R}}$. An orbit or trajectory of a map consists of the sequence of images of a point under iteration of the map: $(f^n(x))_{n \in \mathbb{Z}}$.

A singular point of a differential equation $\dot{x} = R(x, t)$ is a point x for which the right-hand side is zero for all t , that is, an equilibrium, or constant solution, or fixed point. Fixed points of a map f are those points x for which $f(x) = x$. A periodic point is a state that repeats at some positive time. For differential equations, this corresponds to solutions that are periodic functions of time; for maps, these are fixed points of an iterate. For the flow on the cylinder generated by $\ddot{x} + \sin x = 0$, all but four orbits are periodic; the point $(5 + \sqrt{5})/8$ is two-periodic for the map $4x(1-x)$.

Fixed and periodic points can be anchors for the study of the global orbit structure, and therefore, it is important to understand the behavior of nearby orbits. A fixed point is said to be attracting if orbits of nearby

Figure 1. Stable and unstable manifold of a hyperbolic fixed point.

points stay nearby (Poisson stability) and converge to it for large positive time (asymptotic stability). (The example of a circle map like this $\odot$ with a fixed point at the top illustrates that the second condition does not imply the first.) This is the case if the differential of the map (or time-1-map in the case of a flow) at that point has only eigenvalues of absolute value less than 1. If all eigenvalues have absolute value greater than 1 then the point is repelling: There is a neighborhood which every other point leaves in positive time. The map $f_2(x) = 2x(1 - x)$ has 0 and $\frac{1}{2}$ as fixed points. 0 is repelling and $\frac{1}{2}$ is attracting. In fact, $\frac{1}{2}$ is superattracting: $f'_2(\frac{1}{2}) = 0$ and orbits near $\frac{1}{2}$ approach $\frac{1}{2}$ faster than exponentially.

If eigenvalues of the differential are allowed to lie both inside the unit circle and outside it but not on it, then the fixed point is said to be “hyperbolic.” In this case the Hartman–Grobman theorem states that there is a continuous coordinate change that maps orbits near the fixed point to orbits of the linearized map. Moreover, tangent to the contracting and expanding subspaces of the linearization, there are the stable and unstable manifold of points positively and negatively asymptotic to the fixed point, respectively. These are smooth subspaces without self-intersections, but they may be packed into the phase space in a complicated way.

For periodic points of maps, the analysis of stability can be carried out by studying the appropriate iterate; for a flow, one likewise studies Poincaré return maps as follows. Take a small hypersurface through the periodic point transverse (for example, orthogonal) to the flow. The orbit of every point sufficiently near the periodic point returns to this surface at a time close to the period, and this defines a map from a neighborhood of the periodic point in the hypersurface into the hypersurface, with the original periodic point as a fixed point.

If, for example, a periodic orbit is an attracting fixed point for the return map, then it is a limit cycle: All nearby orbits are asymptotic to it. For the mathematical pendulum from the introduction, the circle $\{v = 0\}$ is a

Figure 2. A section.

Figure 3. Two attracting points.

section of the cylinder, and the return map is defined for all of its points. It has two fixed points, and all other points are two-periodic.

A property complementary to stability of a fixed or periodic point as defined in terms of the behavior of nearby orbits (i.e., perturbations of the initial condition) is that of stability under perturbations of the dynamical system. An easy way to guarantee this is *transversality*, which is weaker than hyperbolicity: A fixed point $x = f(x)$ is said to be *transverse* if the derivative of f at x does not have 1 as an eigenvalue. (This implies that there are no other fixed points nearby.) In this case, any C^1 -perturbation of f (i.e., one that changes derivatives only a little) also has a (transverse) fixed point near x . The origin is a nontransverse fixed point of $x(1 - x)$, and indeed, it is absent for $x(1 - x) + \varepsilon$ with $\varepsilon < 0$. The creation of two (hyperbolic) fixed points as ε changes from negative to positive is a basic local *bifurcation*. For differential equations, transversality corresponds to invertibility of the differential of the right-hand side.

An “invariant set” is a union of orbits; for example, $[0, 1]$ is invariant under $4x(1 - x)$. It is a repeller if it has a neighborhood in which only orbits of points in the invariant set stay for all positive time. It is an “attractor” if there is a neighborhood that is mapped into itself and the intersection of whose positive-time iterates is the invariant set. (Usually, one also requires that there is no proper subset with the same property. Thus, Figure 3 shows two attracting fixed points, and the interval with these as endpoints is not considered an attractor.)

The “basin of attraction” is the set of points that are asymptotic to the attractor. For example, the interval $(0, 1)$ is the basin of attraction of $\frac{1}{2}$ for the map $2x(1 - x)$.

Figure 4. The Birkhoff-Smale theorem.

If two hyperbolic fixed points (saddles) in the plane are connected by a curve segment that lies in the unstable manifold of one of them and in the unstable manifold of the other, then this segment is called a “separatrix” (because it often separates two basins of attraction). More generally, the intersection of the stable manifold of one hyperbolic point with the unstable manifold of another is called a “heteroclinic intersection,” and the orbit of every intersection point is called a “heteroclinic orbit.” If the two fixed points coincide then one uses the terms “homoclinic intersection” and *homoclinic orbit* instead. The Birkhoff-Smale theorem asserts that if a homoclinic intersection is transverse (or if there is a pair of transverse heteroclinic intersections, that is, two hyperbolic points such that the unstable manifold of each of them intersects the stable manifold of the other point transversely), then there is a “horseshoe,” that is, a rectangle that (under an iterate) gets mapped across itself in a horseshoe-like fashion as illustrated in Figure 4 and in Anosov and Axiom-A systems. This implies directly that there is an invariant Cantor set on which the dynamical system exhibits deterministic chaos.

There are several ingredients that make up chaotic behavior. One of these is recurrence. There are several recurrence properties. A point is said to be *recurrent* if it returns arbitrarily near to its initial condition. For a rigid rotation of a circle by an irrational number of degrees, all points have this property. By contrast, a point is said to be *transient* or *wandering* if it has a neighborhood all of whose images are pairwise disjoint. For the circle map $\odot$ with a fixed point on top, all nonfixed points are wandering. The set of nonwandering points is called the nonwandering set. Nonwandering orbits can be closed by a localized C^1 perturbation of the map (Pugh closing lemma). A dynamical system is said to be “topologically transitive” if it has a dense orbit and “minimal” if every orbit is dense. Irrational circle rotations have both properties. Minimality does not reflect chaotic behavior. Existence of a dense orbit is equivalent to the condition that for any two

open sets there are arbitrarily large times at which the image of one of these sets overlaps the other. A strengthening of this property is that such overlap occurs for all sufficiently large times; this is called topological mixing and implies sensitive dependence on initial conditions. Following Devaney, one can say that a dynamical system is *chaotic* if it is topologically transitive and the set of periodic points is dense. This also implies sensitive dependence. A condition stronger than sensitive dependence is “expansivity”: There is a universal positive constant by which the images of any two points, no matter how close initially, are separated at some time. The cat map and horseshoes are good examples of dynamical systems with these properties.

The Poincaré return map is not the only construction that produces a new dynamical system with a different phase space. Another straightforward one is the product of two dynamical systems. For example, the flow of rotations of the unit circle given by $x_1 = \alpha \cos t$, $x_2 = \alpha \sin t$ can be combined with a similar flow $y_1 = \omega \cos t$, $y_2 = \omega \sin t$ to a flow on the two-torus in $\mathbb{R}^4$ defined by all four equations. (Note that the plane defined by $y_1 = y_2 = 0$ is a section on which the return map is a time- $2\pi/\omega$ -map of the first flow.) If one projects this to the $x_1 y_1$ -plane, one gets Lissajous figures. In some applications, these readily show whether modes in weakly nonlinear oscillators are locked together.

PHASE-SPACE DIFFUSION AND CORRELATIONS

For problems concerned with particle acceleration and heating, which can be described in two degrees of freedom, surfaces of section in a two-dimensional phase space are usually appropriate for representing the motion (Lichtenberg & Lieberman, 1991, Chapter. 3). For periodically driven systems, a mapping representation is often convenient to describe the motion (See **Fermi acceleration and Fermi map; Standard map**). In the surface of section there is a characteristically divided phase space in which regular Kolmogorov–Arnol’d–Moser (KAM) curves and stochastic trajectories are intermingled. In the globally stochastic region of the phase space for a system with two degrees of freedom, in which KAM curves spanning the phase coordinate do not exist, a complete description of the motion is generally impractical. We can then seek to treat the motion in a statistical sense; that is, the evolution of certain average quantities can be determined, rather than the trajectory corresponding to a given set of initial conditions (Wang & Uhlenbeck, 1945). Such a formulation in terms of average quantities is also the basis for statistical mechanics (see Penrose, 1970, for example). The mathematical foundations for many of the results can be found in Arnol’d & Avez (1968).

In regions in which the trajectories are stochastic, nearby trajectories diverge exponentially in time. The divergence is usually measured by calculating the Lyapunov characteristic exponent σ of a trajectory x and a nearby trajectory $x + w$,

$$\sigma(x, w) = \lim_{t \rightarrow \infty, d(0) \rightarrow 0} \left(\frac{1}{t} \right) \ln \frac{d(t)}{d(0)}, \quad (1)$$

where d is the distance separating the trajectories. Analytical and numerical calculations of the σ ’s (especially the maximum value of $\sigma = \sigma_1$ with respect to variations of w) are widely used as measures of the degree of stochasticity in near-integrable systems. The commonly used numerical procedure for calculating the Lyapunov exponents was developed by Benettin et al. (1976).

In many problems, the density distribution in action space is the important quantity. Its dynamics is simplified by an average over phases to find the dynamical friction and diffusion coefficients for the action, which can then be used for determining its time evolution. If the phases are decorrelated after each mapping step, then a random phase approximation can be used which greatly simplifies the calculation. If the averaging over phase can be performed for

a localized value of the action, then the resulting evolution is a Markov process, leading to the Fokker–Planck equation for the evolution of the distribution (Wang & Uhlenbeck, 1945)

$$\frac{\partial P}{\partial n} = -\frac{\partial}{\partial I}(BP) + \frac{1}{2} \frac{\partial^2}{\partial I^2}(DP), \quad (2)$$

where P is the probability distribution in the action I , B and D are the friction and diffusion coefficients, appropriately averaged over the phases, and n is a characteristic time over which the averaging can be performed. For example, using the standard map

$$\begin{aligned} I_{n+1} &= I_n + K \sin \theta_n, \\ \theta_{n+1} &= \theta_n + I_{n+1}, \end{aligned} \quad (3)$$

then one step of the mapping gives

$$\Delta I_1 = K \sin \theta_0, \quad (4)$$

and the transport coefficients, with phases randomized on each step, are

$$F_{QL} = F = \frac{1}{2\pi} \int_0^{2\pi} \Delta I_1 d\theta_0 = 0, \quad (5)$$

$$D_{QL} = \frac{D}{2} = \frac{1}{4\pi} \int_0^{2\pi} (\Delta I_1)^2 d\theta_0 = \frac{K^2}{4}, \quad (6)$$

where the subscripts QL refer to quasilinear (phase randomized) values with no higher-order correlations. (The factor of 2 difference between D_{QL} and D is a convention.)

Phase correlations, which always exist in a phase space with both regular and stochastic regions, complicate the calculation procedures. Close to the borders between stochastic and regular regions, the correlations become pronounced, requiring entirely different procedures for determining the diffusion. The existence of accelerator modes in the standard map also leads to nondiffusive behavior. Other phenomena of interest for diffusion calculations are the effect of noise and the effect of slow changes of system parameters. For weak correlations, for example, large K in the standard map, corrections to the single-step transport coefficients can be obtained. The corrections were obtained using Fourier techniques by Rechester et al. (1981). In the opposite limit for which a phase-spanning KAM curve (torus) has just been broken, resulting in a cantor (the KAM curve becomes a cantor set), an approximate rate of local diffusion can be calculated. These techniques were developed to analyze the standard map, but can be used in various approximations to describe other two-degree-of-freedom systems. For a review of the various techniques and limitations see Lichtenberg & Lieberman (1991, Chapter 5).

PHASE TRANSITIONS

A phase transition is a change in the degree or nature of order in a system and/or a change in its symmetry caused by a change in a thermodynamic variable such as temperature or pressure. When water freezes as the temperature is lowered, it undergoes a phase transition from a liquid to a solid. In the liquid state, the positions of the water molecules are disordered and the system is isotropic. In the solid state, however, the molecules are fixed at the sites of a crystal lattice, so the system has positional order and the symmetry of the ice lattice. Other examples of phase transitions include the liquid-vapor transition, in which the ordering is related to a change in density of the material; the transition from paramagnet to ferromagnet, which involves the appearance of a net magnetization as the temperature is lowered through the Curie temperature; the isotropic-nematic transition in liquid crystals, in which the rod-like liquid crystal molecules all become oriented in the same direction; and the superfluid transition in liquid helium, in which a macroscopic fraction of the helium atoms condense into a single quantum mechanical energy level. There are many others.

For any phase transition, we can define an order parameter. This is a quantity related to the degree of ordering which changes as the system goes through the transition. One measure of the order in a system is its entropy: a more ordered system has a lower entropy. While the entropy could be used as an order parameter,

it is normally difficult to measure. An order parameter is usually physically measurable and is typically chosen to be zero in the less-ordered phase and nonzero in the more-ordered phase. For the liquid-vapor transition, the order parameter is proportional to the difference in density between the liquid and vapor phases. The order parameter for the ferromagnetic transition is simply the magnetization. For the superfluid transition in liquid helium, the order parameter is a complex number describing the macroscopic wave function of the superfluid.

Phase transitions can be classified as first order or second order. The terminology refers to the fact that certain derivatives of the free energy are discontinuous at a phase transition. In a first-order transition, it is the first derivatives (entropy, density, magnetization) that are discontinuous, while in a second-order transition, the discontinuity occurs in the second derivatives. A more practical classification is in terms of the behavior of the order parameter. At a first-order transition, the order parameter changes discontinuously. These transitions exhibit hysteresis and a latent heat resulting from the discontinuous change in entropy. At a second-order transition, the order parameter changes continuously; there is no hysteresis and no latent heat. In equilibrium, a thermodynamic system has a well-defined free energy and stable states correspond to absolute minima of this free energy. At a phase transition, the position of the free energy minimum changes, corresponding to a change in phase.

A phase diagram for a typical liquid-vapor system is shown in Figure 1(a). In the pressure-temperature plane, there is a line of first-order phase transitions which ends at a point at which the transition is second order. The same system is shown in the temperature-density plane in Figure 1(b). The region under the coexistence curve in Figure 1(b) is forbidden; there are no stable states in this region. When the mean properties of the system would place it inside this curve, the system phase separates into coexisting liquid and vapor phases with different densities lying on the coexistence curve itself. In the center of this region, the high-temperature phase is globally unstable, while closer to the edge, it is metastable. A supersaturated vapor would lie in this metastable region.

Points in the phase diagram at which second-order transitions occur are called critical points. At these points, the equation of state of the system takes on a special form, and the order parameter and other thermodynamic quantities show a power law dependence on the distance from the critical point. For example, if we consider a magnetic system with magnetization M , temperature T , and Curie temperature T_c , then the magnetization behaves as $M \sim [(T_c - T)/T_c]^\beta$ for $T \leq T_c$. The magnetic susceptibility $\chi = dM/dH$, where H is an applied magnetic field, diverges at the critical point as

Figure 1. A typical liquid–vapor-phase diagram. (a) In the pressure–temperature plane a first-order phase transition occurs on crossing the solid line. The line of first-order transitions ends at the critical point C, at which the transition is second order. (b) The same phase diagram is shown in the temperature–density plane. The solid curve is the coexistence curve and corresponds to the solid line in (a). Outside the coexistence curve, the system exists as a single phase. In the region labeled U the one-phase state is unstable, and in the region labeled M it is metastable. If the system is cooled from the one-phase state at point T_1 into the unstable region at T_2 , it will phase separate into a liquid component at the point L coexisting with a vapor component at V.

$\chi \sim |(T_c - T)/T_c|^{-\gamma}$. The quantities β and γ are called critical exponents. Interestingly, while T_c is different for different materials, the exponents β and γ have the same values for many different systems, including Ising ferromagnets and liquid–vapor systems, among others. This is known as “universality.”

The simplest theoretical models used to describe phase transitions are called mean field theories. The van der Waals model for the liquid–gas transition and the Curie–Weiss model for the ferromagnetic transition are examples. Such theories assume that the order parameter at a particular point is determined by the average properties of the system—that is, by a mean field due to all other points of the system. Mean field theories are capable of describing first- and second-order-phase transitions qualitatively, but the values of the critical exponents are, in general, wrong. This is because mean field theories explicitly neglect the effects of spatial fluctuations in the order parameter, whereas it is these fluctuations which determine the behavior of the system near the critical

point. Renormalization group theory provides a more complete description of critical point behavior.

When a system is quenched below a phase transition by suddenly changing a thermodynamic variable—for example, by suddenly dropping the temperature below the phase transition in a liquid–vapor system—it separates into two distinct phases. If the system is quenched into a region where the high-temperature phase is metastable (Figure 1), then macroscopic phase separation can only occur once large enough droplets of the unstable phase nucleate and grow. If it is quenched in the unstable region, then phase separation occurs by a process known as spinodal decomposition, whereby initially small perturbations to the local order parameter grow and coarsen with time. In a system with a conserved order parameter (e.g., a binary fluid mixture, in which the amount of each substance is fixed), the size of domains grows with time t as $L \sim t^{1/3}$, while if there is no conservation law (e.g., a ferromagnet) then $L \sim t^{1/2}$.

Phase transitions can also occur in systems out of equilibrium, for example, in the presence of a temperature gradient or a time-varying field. An important and interesting aspect of non-equilibrium systems is that the state of the system is no longer governed by the minima in the free energy, and indeed, a free energy functional may not even exist. Phase transitions can be significantly modified by non-equilibrium effects. In the case of a magnet in a time-varying field, for example, a competition between the time scale of the variations in the external field and the intrinsic relaxation time of the system itself leads to new behavior including spontaneous ordering that is not observed in the static case. Rather different phenomena, such as pattern-forming bifurcations in driven fluid systems, can also be thought of as nonequilibrium phase transitions.

PHOTONIC CRYSTALS

Photonic crystals are periodic dielectric (and/or metallic) structures, with periodicity comparable to a wavelength λ of interest, forming a *designable* optical medium where light propagation can exhibit unusual properties (Joannopoulos et al., 1995). The most important such property is a photonic band gap: a range of wavelengths in which there are no propagating modes in the crystal. Light in the band gap decays exponentially in the crystal, which acts like an optical “insulator.” Nonlinear devices can exploit photonic crystals for enhanced phase sensitivity as well as to reduce power requirements, by means of tight spatial and long temporal confinement using the band gap and/or slow-light phenomena. Below are outlined two archetypal devices that greatly benefit from these properties of photonic crystals: Mach–Zender interferometers and bistable switches.

The simplest photonic crystals are one-dimensionally periodic multilayer films, or “Bragg mirrors,” which were first studied in crystalline minerals by Lord Rayleigh (1887) (who observed that *any* periodic index variation will induce a band gap along that direction) and have since been the basis for a wide variety of applications: from reflective dielectric coatings, to distributed Bragg feedback (DFB) lasers, to fiber Bragg gratings for dispersion compensation and filters. It was not until 1987, however, that Yablonovitch (1987) and John (1987) applied the full principles of solid-state physics to electromagnetism and suggested that a three-dimensional (3-d) crystal could produce an omnidirectional gap. Since then, many photonic-crystal structures have been studied, both theoretically and experimentally, in two and three dimensions.

As a particular example, we consider a *two-dimensional* photonic crystal consisting of a square lattice of dielectric cylinders in air. This structure has a band gap for transverse-magnetic (TM) light (electric field perpendicular to the plane) and can, therefore, confine cavity and waveguide modes in point-like and linear defects of the crystal, as in Figures 1 and 2. For example, a single “defect” rod can be increased or decreased in size to trap a cavity mode within a diameter $\sim \lambda/2$, or a row of defect rods to form a waveguide. Bloch’s theorem from solid-state physics (Ashcroft &

Figure 1. (Top) Schematic of a Mach–Zender interferometer: a waveguide that is split and recombined, with the relative phase modified by an active region to control the output transmission. Inset: a CCW slow-light waveguide to take advantage of photonic crystals. (Bottom) Band diagram of the CCW waveguide showing typical cosine dispersion curve. Because of the low group velocity, a slight shift of the curve (dashed) will cause a large change Δk in the wave number (horizontal axis). (The units are in terms of the distance a , the period of the square lattice.)

Mermin, 1976) implies that modes in such a periodic waveguide propagate *without reflections*. Moreover, the waveguides form an effectively one-dimensional system, since the gap prohibits lateral scattering—this property allows photonic-crystal waveguides and cavities to be combined into complex device networks by adhering to simple design rules and symmetries. Alternatively, one can make a periodic sequence of cavities to form a coupled-cavity waveguide (CCW)—light slowly leaks from one cavity to the next, again trapping a guided mode (Yariv et al., 1999). The same principles apply in other photonic crystals, including those in three dimensions, and a direct analogue of this 2-d crystal can be made in 3-d (with an omnidirectional gap) by a stack of 2-d-like layers (Johnson & Joannopoulos, 2002).

Mach–Zender Interferometers

The foundation of many optical device designs, from modulators to optical logic to switching, is the well-known Mach–Zender interferometer (Saleh & Teich, 1991) (Figure 1, Top).

Here, light in an incident waveguide is split into two branches and then recombined. If the two branches have the same optical path length, the recombination is in phase and light is transmitted; if their paths differ by half a period, then the recombination is out of phase and light is reflected. The relative optical path length is altered, for example, by changing the index by some Δn in the

branches with a linear electro-optic (external) or Kerr (self-induced) modulation, allowing the transmission to be switched continuously from “on” to “off.” By using photonic-crystal line-defect waveguides in the interferometer, one can take advantage of their low group-velocity capability to significantly lower the power and size requirements of the device by a factor of the group velocity or better (Soljačić et al., 2002b).

To attain a low group-velocity waveguide in a photonic crystal, one simple strategy is to employ a coupled-cavity waveguide (CCW) like that in Figure 1 (top). The guided band of such a waveguide has a characteristic cosine-curve dispersion relation (Figure 1, bottom) with two important properties: (i) the mid-band group velocity is low and decreases exponentially with the cavity separation, and (ii) the group-velocity dispersion (frequency derivative of the group velocity) is zero at the center of the bandwidth, minimizing signal distortion.

Because the group velocity v_g is low, when the dispersion curve $\omega(k)$ (frequency vs. wave number) is slightly shifted by altering the index n of a waveguide branch, there will be a large change in k (Figure 1, bottom), causing a corresponding large phase shift $\Delta\phi = \Delta k L$ (where L is the propagation distance). Mathematically, if the curve is shifted by $\Delta\omega \sim \Delta n \omega$, then the phase shift is $\Delta\phi \cong L \Delta\omega / v_g$, inversely proportional to group velocity $v_g = d\omega/dk$. This means that the device size L to achieve a fixed phase shift $\Delta\phi = \pi$ (with a given Δn) varies proportionally to v_g . Moreover, the power required to modulate the index is proportional to L , so the switching power is also proportional to v_g . Alternatively, one could keep L fixed and reduce Δn by a factor of v_g ; for a linear (Pockels) modulation, this reduces the modulation power by v_g^2 .

If the Mach–Zender interferometer is modulated by the optical waveguide signal itself, say for all-optical logic, then there is an analogous benefit: the light is compressed in time by a factor of v_g/c , causing a greater field $|E|^2$ for the same input power. Combined with the above mentioned power savings from length reduction, this means that Kerr self-modulated devices have their power reduced proportionally to v_g^2 .

Of course, the low group velocity comes at a price: the bandwidth of the waveguide is reduced proportional to v_g . In optical telecommunications systems, however, the required bandwidth is relatively small; for example, a 40 Gbit/s channel has a bandwidth $\Delta\omega/\omega \sim 1/3000$, meaning that the group velocity could potentially be lowered by several hundred times without limiting the bandwidth, with corresponding decreases in the device size and power relative to conventional waveguides.

Optical Bistability

Optical bistability is a dramatic nonlinear phenomenon that can be exploited to implement all-optical transis-

tors, switches, logic gates, amplifiers, and other functions (Saleh & Teich, 1991). Bistability stems from nonlinear feedback combined with resonant transmission through a cavity, produces an output power that is a sharp nonlinear function of input power, and may even display a hysteresis loop (Figure 2, right).

In this context, the ability of photonic crystals to minimize both cavity modal volume V and lifetime Q (number of temporal periods for energy to decay by $e^{-2\pi}$) simultaneously allows them to greatly reduce the power threshold for optical bistability, in principle even down to the milliwatt level (Soljačić et al., 2002a).

An archetypical bistable device consists of an input waveguide coupled symmetrically into an output waveguide via a resonant cavity; this is shown in a photonic crystal setting of line and point defects in Figure 2 (left). In any such system, the transmission spectrum as a function of frequency will be a Lorentzian-like curve, peaked at 100% (in the absence of other loss mechanisms) at the resonant frequency (Figure 2, middle). In order to achieve bistability, one must include nonlinear feedback: the index (and thus the frequency) of the cavity depends on the field strength (e.g., via a Kerr nonlinearity $\Delta n \sim |E|^2$). Furthermore, one must operate at a frequency ω_0 that lies *below* the linear resonant frequency ω_{res} . This combination, for continuous-wave (CW) sources, results in the bistable power-response curve shown in Figure 2 (right), which here includes a hysteresis. There are two stable system states for input powers in the bistable region (between the dashed vertical lines), and which one is realized depends upon whether one started from low or high power. (The middle, dashed, branch of the “S” curve is unstable.)

Intuitively, as the input power grows, the increasing index due to the nonlinearity will lower the resonant frequency through ω_0 , as depicted by the dashed line in Figure 2 (middle), causing a rise and fall in transmission. This simple picture, however, is modified by feedback: as one moves into the resonance, coupling to the cavity is enhanced (positive feedback), creating a sharper “on” transition; and as one moves out of the resonance, the coupling is reduced (negative feedback), causing a delayed “off” transition.

The power threshold for the onset of bistability depends upon the power required to shift the cavity index sufficiently, which in turn depends upon the nonlinearity of the materials and the field strength $|E|^2$ inside the cavity for a given input power. This field strength is inversely proportional to the modal volume V and is proportional to the lifetime Q (over which time the field builds up in the cavity). On the other hand, the required index shift of the cavity is proportional to the frequency width $1/Q$ of the Lorentzian transmission spectrum. Ultimately, therefore, the threshold power is proportional to V/Q^2 ; these simple arguments are confirmed by a more detailed analytical

Figure 2. (Left) 100% (peak) resonant transmission from an input to an output waveguide through a cavity, formed by line and point defects, respectively, in a photonic crystal. Shaded regions indicate alternating positive/negative fields. (Middle) Lorentzian transmission spectrum (solid curve) of the linear resonant system. Increasing the power will nonlinearly shift the resonance curve (dashed) towards the operating frequency ω_0 . (Right) Bistable transmission curve of output vs. input power resulting from the resonant transmission plus nonlinear feedback. The curve is an analytical theory and the dots are numerical calculations, with the vertical dashed lines indicating the region of hysteresis—for open dots the power was increased from a low value, while for closed dots the power was decreased from a high value.

theory that accurately predicts the bistability curve from the cavity characteristics (Soljačić et al., 2002a). Unlike traditional cavities such as ring resonators, photonic crystals impose no tradeoff between V and Q —the lifetime Q can be increased arbitrarily (up to the required signal bandwidth) while V is maintained near its minimum of $\sim (\lambda/2n)^3$, where n is the index of refraction. Indeed, in the example system of Figure 2, assuming reasonable material parameters and a $Q = 4000$ determined by the telecommunications bandwidth, one obtains a theoretical operating power of only a few milliwatts.

We conclude by presenting an analytical formula, derived from coupled-mode theory and perturbation theory, for the CW bistability relation in Figure 2 (right). The input/output power relation is given by

$$\frac{P_{\text{out}}}{P_{\text{in}}} = \frac{1}{1 + (P_{\text{out}}/P_0 - \delta)^2},$$

where δ is the frequency-detuning parameter $\delta \equiv 2Q(\omega_0 - \omega_{\text{res}})/\omega_{\text{res}}$ and P_0 is the characteristic power for bistability:

$$P_0 \equiv \frac{1}{\kappa Q^2 (\omega_{\text{res}}/c)^{d-1} \max(n_2)}.$$

Here, d is the dimensionality of the system, n_2 is the Kerr coefficient (index change per unit intensity of light), and κ ($\sim 1/V$) is a dimensionless, scale-invariant “nonlinear feedback parameter” quantifying the concentration of the cavity field E in the nonlinear material.

PLASMA SOLITON EXPERIMENTS

Comprising a very large number of charged particles within a confined volume, a plasma is a convenient laboratory facility in which both linear and nonlinear phenomena can be experimentally investigated. The overall plasma is electrically neutral in that the density of positive particles is equal to the density of negative particles. If the negative particles are electrons, this is called a two-component or normal plasma. If a certain fraction ε of the electrons is replaced with negative ions, this is called a three-component or a negative ion plasma.

Washimi and Taniuti (1966) were the first to demonstrate that the evolution of perturbations of the charge density in a normal plasma can be described by the nonlinear fluid equations for the ions. This description includes a Boltzmann assumption for the electrons and Poisson's equation to reflect the local charge nonneutrality in a density perturbation that can be described with the Korteweg-de Vries (KdV) equation,

$$\frac{\partial \psi}{\partial t} + \psi^\nu \frac{\partial \psi}{\partial x} + \beta \frac{\partial^3 \psi}{\partial x^3} = 0. \quad (1)$$

Here the dependent variable ψ represents the perturbations in the ion density, ion velocity, or the electric potential; β is a constant; and the parameter $\nu = 1$.

In 1984, Watanabe showed that perturbations in a negative ion plasma can also be described by the same equation if the fraction ε has certain values. In particular, if this parameter is very large, then the negative ions predominate and rarefactive solitons evolve from a negative ion density perturbation. Because the mass of the negative ions could be comparable with the mass of the positive ions, he found that the parameter ε had a critical value ε_c at which the derivation led to a modified Korteweg-de Vries (mKdV) equation with the parameter $\nu = 2$. Both of these equations describe solitons that propagate in one direction.

The first extension to include effects of higher dimensions was performed in 1970 by Kadomtsev and Petviashvili, who included weak effects in a direction that was perpendicular to the dominant direction of propagation of the ion acoustic soliton. This equation is now called the Kadomtsev-Petviashvili (KP) equation for $\nu = 1$ in a normal plasma and the modified Kadomtsev-Petviashvili (mKP) equation for $\nu = 2$ in a negative ion plasma; thus

$$\frac{\partial}{\partial x} \left(\frac{\partial \psi}{\partial t} + \psi^\nu \frac{\partial \psi}{\partial x} + \beta \frac{\partial^3 \psi}{\partial x^3} \right) + \frac{\partial^2 \psi}{\partial y^2} = 0. \quad (2)$$

Both of these equations have certain predictions that have been experimentally verified in a plasma.

Figure 1. Evolution of a positive ion perturbation in a normal two component plasma. The pictures are taken at increasing distances from the source and illustrate the evolution of a burst of ions into a number of KdV solitons.

Laboratory experiments require the creation of a large volume of uniform collisionless plasma in which localized density perturbations are launched and movable probes monitor the evolution of the perturbation. Collisions between the particles are reduced with the evacuation of the chamber to a low pressure. Typically, a gas such as argon is inserted into the chamber and ionized to create a plasma with a volume of approximately 1 m^3 . The density perturbations are created by applying a voltage signal to a fine-mesh grid or by introducing a charge density perturbation from one plasma into a second plasma. This is called a double-plasma (DP) machine and plasma solitons were first observed in a DP machine (Ikezi et al., 1970).

The spatial and temporal evolution of a compressive density perturbation in a normal plasma is illustrated in Figure 1. As this perturbation moves in the plasma, a number of solitary waves emerge for which the following KdV soliton properties have been observed: the product of its width (W) times the square of its width (W^2) is constant, and the soliton velocity $c_s = [1 + \psi/3]c$ where c is the linear ion acoustic velocity. In addition, the nondestructive collision of two solitons with different amplitudes was verified in the initial experiment performed in a normal plasma that existed in the DP machine.

By replacing a certain fraction of the free electrons in the normal plasma with negative ions to which these free electrons become attached, it is possible to realize a negative ion plasma. As a gas such as sulfur hexafluoride has a large attachment coefficient, a negative ion plasma can be created that consists of positive argon ions and negative fluorine ions whose

masses are comparable. The parameter ε can be altered to have values of $\varepsilon < \varepsilon_c$, $\varepsilon = \varepsilon_c$, or $\varepsilon > \varepsilon_c$. In the first case, the positive ions are compressed and the normal KdV soliton is excited. KdV solitons are also excited in the third case due to compression of the negative ions. In the second case, mKdV solitons have been excited and their properties have been verified. In particular, it was observed that the product of ψW^2 is constant. The first experimental detection of solitons in a negative ion plasma was in a DP machine (Ludwig et al., 1984; Nakamura & Tsukabayashi, 1984), and both solitons were later detected in a negative ion plasma using the grid excitation mechanism (Cooney et al., 1991).

Two solitons that propagate in a normal plasma or in a negative ion plasma but in directions that are not collinear can still interact and are described by the KP equation. In particular, Miles (1977) noted that at a particular angle, the amplitude of the soliton after such an interaction would be greater than the sum of the amplitudes of the two solitons that preceded the interaction. If the amplitudes of these two initial solitons were equal, the amplitude of the new soliton would be 4 times this amplitude. The critical amplitude and the amplitude enhancement predicted from this resonant interaction was first experimentally examined in a normal plasma (Ze et al., 1979). In the negative ion plasma, an amplitude enhancement of two was anticipated and has been experimentally verified (Nakamura et al., 1999).

A laboratory plasma has been found to be a convenient venue in which several of the fundamental properties of solitons that are described with the KdV, mKdV, KP, or mKP equations can be experimentally studied and verified. A summary of other experiments has recently appeared (Lonngrén, 1998).

PLUME DYNAMICS

Plumes and jets are naturally and frequently occurring transport phenomena arising in a variety of settings, ranging from dry convecting atmospheric motion on hot days through explosive volcanic eruptions, for example, the 1915 eruption of Lassen Peak shown in Figure 1. The fluid dynamical purpose of a plume is dynamic equilibration of a localized unstable distortion of the fluid density, which results in vertical, coherent motion of a parcel of fluid seeking an equilibrium density. Viscosity couples and draws fluid along with the parcel on its voyage (turbulent entrainment). If the parcel is miscible with the ambient fluid, turbulent mixing will result, accelerating the equilibration process.

A further complication is that ambient fluids typically develop stable stratifications in which the fluid density is higher at the bottom. Such is the case with the Earth's atmosphere, whose density drops to zero in outer space, and the steady-state density profile is merely the thermodynamic response of an air layer under gravitational compression. Equally interesting stratification processes occur with much sharper gradients in convective boundary layers and in the thermoclines found in lakes and oceans. In these situations, stable transitions from a high-density bottom fluid layer to a low-density upper fluid layer may occur across a very sharp, nearly interfacial, layer. Typical stratifying agents include localized high temperature and/or concentration gradients (e.g., salt in the ocean). The modifications introduced by such layers can be both naturally dramatic and socio-economically challenging. The discharge of pollutants into the atmosphere, lakes, and oceans

Figure 1. May 22, 1915, eruption of Lassen Peak, taken 50 miles away in Anderson, California, by photographer, R.I. Meyers. (Thanks to Cari Kreshak and Lassen Volcanic National Park for providing the high quality image.)

is frequently accompanied by trapping phenomena directly attributed to the formation of such stable density layers (thermal inversions), in which the discharged pollutants are confined away from mixing flows and may lead to hazardous air and water quality.

Plume Mixing and Entrainment: Modifying the Large Scale Observables

A light plume of fluid in a constant density environment is expected to rise continually until the Archimedian buoyancy force is reduced through mixing of the plume with the ambient to levels at which viscous balances occur. The complete evolution requires, at minimum, the solution of the Navier–Stokes equations, with an evolving density anomaly (the plume) allowed to mix with the ambient. The mixing is turbulent, and the computational simulations of these nonlinear partial differential equations are both difficult, and necessary in making first principle predictions. Modelers have turned to alternative, somewhat ad hoc, yet nonetheless fundamental attempts to describe the evolution with fewer degrees of freedom than the complete fluid equations. As discussed below, the pioneering work of Morton et al. (1956) utilized an entrainment hypothesis with a single entrainment coefficient in an attempt to describe jet (plume) profiles by reduced, nonlinear ordinary differential equations (involving only a few degrees of freedom).

The plume dynamics in stratified fluids are dramatically different (Morton et al., 1956; Morton, 1967; Turner, 1995). In such a situation, the buoyancy of a plume of light fluid is strongly height-dependent, and an initially (low altitude) light fluid parcel may well rise to a height at which a buoyancy reversal occurs and the parcel becomes neutrally buoyant. Such a situation was originally noted by Morton et al. to cause an arrestment of vertical jets of light fluid. Their experiments and modeling for a fluid with a linear stratification (linearly

decreasing density with increasing height) indeed show vertical jets arresting. The implications for functioning smokestacks, modeling of volcanic plumes (Sparks et al., 1997), and the mixing of oceanic pollutants (Fischer et al., 1979) is clear.

When the density transitions sharply between two distinct values, one finds mixing between low-density jet (or plume) fluid and the ambient fluid, which may dramatically affect the large scale observables. Experiments, performed in the UNC Applied Mathematics Fluid Lab, further exhibit the need for improved modeling that is specifically designed to better understand turbulent mixing and entrainment.

Figure 2 shows two vertical jets, fired at approximately the same volumetric flow rate (roughly 0.2 gal/min) into two identically stratified fluid tanks with a prepared sharp transition from 1.06 g/cm^3 at the bottom to 1.015 g/cm^3 using varying salt concentrations, with a transition of approximately 1 in, thickness, centered around the 14 in. tick on the tape. The left jet fluid is a gauge oil, with density 0.8 g/cm^3 (lighter than all ambient tank fluid). Recall that oil and water do not mix. The right jet fluid is a dyed alcohol–water mixture, with density 0.8 g/cm^3 , also (initially) lighter than everything in the tank. In this case, the alcohol–water mixture may mix with the ambient fluid.

Observe the striking difference in large-scale observables: The nonmixing case penetrates clear to the free surface, whereas the mixing case does not penetrate, but forms, at altitudes in the vicinity of the sharp density transition, a cloud. The alcohol jet, fired in nonstratified cases of either 1.06 g/cm^3 or 1.015 g/cm^3 constant density tanks will reach the free surface at these flow rates and does not form a cloud, which demonstrates the powerful effect that an ambient sharp stratification can have upon plume dynamics, and the effect of the turbulent mixing and entrainment. There has been considerable work on developing plume models for studying the types of behavior shown with the alcohol jet following the original work of (Morton et al., 1956; Sparks et al., 1997; Caulfield & Woods, 1998), and some attempts have been directed at the multi-phase aspects of the oil jet example (Asaeda & Imberger, 1993; Socolofsky et al., 2001). A successful and complete modeling approach handling a full range of cases in which the mixing properties between jet fluid and ambient fluid may be continuously varied is an open challenge.

Dynamic Plumes and Solid Wall Interactions: Transient Levitation of Falling Bodies

As an extreme example in which the injected quantity cannot mix with the ambient fluid, consider recently obtained experimental results concerning the motion of falling bodies through stratified fluids (similar to

Figure 2. Vertical buoyant jets through a strong stable density step: Left is oil (0.8 g/cm^3), right is alcohol-water mixture (0.8 g/cm^3). (Thanks to former UNC undergraduates Ryan McCabe and Daniel Healion for assistance with the experiment.)

the tank setup in Figure 2) (Abaid, Adalsteinsson, Agyapong, McLaughlin, 2004). This study has focused upon the effect of self-generated plumes upon the falling body and has documented situations in which a falling body may generate a dynamic plume that through hydrodynamic coupling, may temporarily arrest the body. Of course, any body moving through a fluid experiences a hydrodynamic drag (which sets terminal velocities of falling bodies) in which the viscous boundary condition of vanishing fluid flow at the solid boundary necessarily drags a blob of ambient fluid along the moving body. In a constant density fluid, there is no potential energy cost associated with moving such a parcel of ambient fluid vertically. However, in strongly stratified fluids, a parcel of fluid moved from one altitude to another may develop a potential energy (buoyancy), as when the body falls through a sharp density transition layer. The momentum of the attached blob of fluid thrusts it into the lower (heavier) fluid, at which point the blob becomes a density anomaly and rises sharply. This motion in turn drags the falling body along with it.

Figure 3 shows three montages of a descending sphere at uniformly spaced times. The (5 mm radius) sphere in this case has a density of 1.04 g/cm^3 and is falling in a stratified tank whose top is fresh water (0.997 g/cm^3) and whose bottom is salt water (1.039 g/cm^3), again with a transition thickness of approximately 1 in. The top montage demonstrates the arrest and transient rise of the initially falling bead, and subsequent return to slow descent, each image uniformly spaced 1.5 s apart. The bead ultimately comes to rest at the tank bottom. The middle montage is the same as the top, only uniformly spaced at 0.1 s intervals. The lower montage has the same time sequence as the middle row, only focusing upon the shadow on the back of the tank, which highlights the entrained, plume-forming fluid.

The nature of this phenomenon is both nonlinear and dynamic. The nonlinear effect of such plumes upon

Figure 3. Top: Digital snapshots of bead position on uniform 1.5 s intervals, Middle: uniformly spaced on 0.1 s intervals, Bottom: shadowgraph depicting the dynamic plume on same time interval as middle row (Abaid, Adalsteinsson, Agyapong, McLaughlin, 2004). (Thanks to David Adalsteinsson for help with formatting the collage in his DataTank program and thanks to former UNC undergraduate Nicole Abaid for assistance with the experimental effort.)

the motion of solid bodies has been incorporated in a reduced system of ordinary differential equations in which the drag law for the falling body is modified to account for the dynamics of the plume which may modify the relative velocity of the falling sphere (Abaid, Adalsteinsson, Agyapong, McLaughlin, 2004). To describe the detailed dynamics of such transient plumes is quite difficult. Historically, there has been more success in the modeling of plume geometries under steady-state geometries. In pioneering work, Morton, Turner, and Taylor (Morton et al., 1956; Morton, 1967; Turner, 1995) were the first to model maintained plumes using an entrainment hypothesis which has become a standard in many fields (Fisher et al., 1979; Sparks et al., 1997).

Steady Plume Models in Stratified Environments

In 1956, Morton, Turner, and Taylor introduced what has become the standard maintained plume models for the shape of jet plumes (plumes emanating from

a maintained source of buoyancy and momentum) (Morton et al., 1956; Morton, 1967; Turner, 1995; Fischer et al., 1979; Sparks et al., 1997; Socolofsky et al., 2001). The entrainment hypothesis assumes that the rate of inflow of diluting, ambient fluid is proportional to the vertical velocity of the jet along its centerline. Much empirical data has been collected exploring the exact dependence of the constant of proportionality upon the various physical parameters describing the jet configuration (stratified profile, jet speed, jet fluid density). A considerable effort since the original work of Morton et al. has addressed the many algebraic fits for the entrainment coefficient as a function of Richardson numbers, etc. (Fischer et al., 1979; Turner, 1995; Socolofsky et al., 2001).

Armed with this entrainment assumption, Morton et al. (1956) developed the following system of nonlinear ordinary differential equations, the solution of which yields the jet (plume) profile in steady state:

$$\frac{d(b^2 w)}{dz} = 2\alpha b w, \quad (1)$$

$$\frac{d(b^2 w^2)}{dz} = 2g\lambda^2 b^2 Q, \quad (2)$$

$$\frac{d(b^2 w Q)}{dz} = \left(\frac{(1 + \lambda^2 b^2 w)}{\lambda^2 \bar{\rho}} \right) \frac{d\rho_0}{dz}. \quad (3)$$

Here, the plume parameters are the center-line vertical velocity, $w(z)$, the plume radius $b(z)$, and the nondimensional plume density $Q(z)$. All are functions of the height variable z . The entrainment coefficient is α , which in neutrally stratified cases is empirically seen to be approximately 0.08 (Fischer et al., 1979; Turner, 1995). The gravitational constant is g , $\bar{\rho}$ denotes some constant reference density, and the ambient stratification is contained within the given profile $\rho_0(z)$.

This system is based on the following assumptions. First, vertical derivatives of certain horizontally averaged, low-order moments (for plume mass, momentum, and buoyancy) are simplified in terms of single point, centerline field variables. Second, radial profiles for plume vertical velocity and buoyancy are postulated in terms of "collective variables": $w(z) = \hat{w}(z) f(r/(ab(z)))$ and $Q(z) = \hat{Q}(z) f(r/(cb(z)))$. Through these, the integrals defining the moments may be directly calculated, leading to the closed system of differential equations given above. For both velocity and plume density, the functional forms are taken to be Gaussians, following empirical observations (Morton, 1967; Fischer et al., 1979; Turner, 1995). The ratio of the velocity length scale a , to plume length scale c is $\lambda = c/a$ is taken to be approximately 1.2, but this must certainly vary considerably upon the mixing properties of the plume fluid with the ambient. Each of these steps involves numerous approximations, an excellent list of which may be found

discussed in Chapter 9 of the text by Fischer et al., along with asymptotic solutions for limiting cases (Fischer et al., 1979).

The solution of these equations gives a rough picture for plume shapes in the environment and typically shows plumes arresting at heights below their heights of static neutral buoyancy (in the absence of any mixing) in stratified environments. A more systematic mathematical reduction of this system from the complete equations, along with a numerical simulation of the complete fluid equations for multiphase fluid flow would be valuable.

POINCARÉ THEOREMS

One of the greatest of all French mathematicians, Jules Henri Poincaré (1854–1912) graduated from the École Polytechnique in Paris and later studied at the École des Mines. In 1879, he became a docteur es sciences at the University of Paris, where he was appointed as a professor in 1881. Poincaré became a member of Académie des Sciences in 1887.

A mathematical genius of rare power, Poincaré's approach to science was to solve concrete problems arising from mathematics, mechanics, and physics, rather than to present his results in a "pure axiomatic form." However, a complete understanding of Poincaré's scientific works has yet to be achieved. Outside mathematics, Poincaré is also known for his works in theoretical physics including his seminal contribution in the special theory of relativity (1904–1905) and for his works on the philosophy of science.

Many of Poincaré's papers gave birth to whole new branches of mathematics, a prime example being algebraic topology, but the matter that occupied his life throughout was the geometrical approach to nonlinear differential equations—in particular, the long-time behavior of orbits of the Newtonian N -body problem in celestial mechanics.

The qualitative approach to nonlinear dynamics, introduced by Poincaré in his seminal papers "Mémoire sur les courbes définies par une équation différentielle" (1881–1886), which focuses on orbits rather than formulas was of a geometric and global nature. This is how the qualitative theory of ordinary differential equations was born.

Studying smooth vector fields on the plane, he classified their simplest equilibria (i.e., points where the given vector field vanishes): foci, nodes, saddle points, and centers. The typical smooth planar vector field has only the first three types of equilibria, but those of a more complicated nature are not excluded.

Poincaré outlined the proof that if a half trajectory γ of the planar vector field v is confined in a compact domain K in which v is free of equilibrium points, but the whole trajectory γ is not confined in K , then K contains a closed orbit of v to which γ is asymptotically attracted (the Poincaré–Bendixson theorem in its simplest form). This type of closed orbit is called a limit cycle.

To generalize, let v be a smooth vector field on a two-dimensional compact manifold M . To each isolated equilibrium p of v , Poincaré associated an integer $\text{Ind}(v, p)$, called the index of v at p , which is defined as follows. Let J be a small loop surrounding the isolated equilibrium p , and let $\Delta\theta$ be the total change of the angle θ that the vector of v makes with some fixed direction when one runs counterclockwise along the loop J . This number is independent of the choice of loop. The index of p is the number $\Delta\theta/2\pi$ which is always an integer. (The index of a focus,

center, or node is $+1$, and the index of a saddle point is -1 .)

If v has only a finite number of equilibria $p_1, \dots, p_r$, then Poincaré showed that

$$\sum_{i=1}^r \text{Ind}(v, p_i) = \chi(M), \quad (1)$$

where $\chi(M)$ is the Euler–Poincaré characteristic of M and no restrictions are imposed on the nature of equilibria $p_1, \dots, p_r$. This result was generalized later by Heinz Hopf to the case of vector fields on compact manifolds of arbitrary dimension and is now called the Poincaré–Hopf theorem.

For a sphere, we have $\chi(M) = 2$, that is, an arbitrary smooth vector field on a two-dimensional sphere must vanish in at least one point—one cannot even comb the hair on a sphere! Another consequence of this theorem is that, for example, on the two-dimensional sphere, one cannot have a smooth vector field having as equilibria only two saddle points or having only three centers.

Poincaré's investigations of celestial mechanics led him to the study of Hamiltonian systems with n degrees of freedom

$$\frac{dq_i}{dt} = \frac{\partial H}{\partial p_i}, \quad \frac{dp_i}{dt} = -\frac{\partial H}{\partial q_i}, \quad i = 1, \dots, n \quad (2)$$

with an analytic Hamiltonian function $H(q, p)$, $(q, p) \in \mathbb{R}^{2n}$. His researches in this area were summarized in his epoch-making three-volume treatise "Les méthodes nouvelles de la mécanique céleste" (1892, 1893, 1899).

The study of Hamiltonian systems close to integrable ones was called the "general problem of dynamics" by Poincaré. Specifically, he studied Hamiltonian equations (2) with a perturbed Hamiltonian of the form

$$H(q, p, \varepsilon) = H_0(p) + \varepsilon H_1(q, p) + \varepsilon^2 H_2(q, p) + \dots, \quad (3)$$

where $H_1, H_2, \dots$ are periodic functions with respect to q of the same period. The system obtained by setting $\varepsilon = 0$ is integrable, and the phase space is foliated by n -dimensional invariant tori $p = \text{const}$. For small nonzero ε , system (2) usually becomes non-integrable. In the case of two degrees of freedom, this means that the Hamiltonian function H is the only first integral of Equations (2) that is an analytic and uniform function of variables q, p and ε .

Poincaré's participation in a mathematical competition organized in 1885 by Oskar II, King of Sweden and Norway, led him to the discovery of homoclinic orbits and related phenomena explaining how a very complicated behavior now called dynamical chaos, occurs in nonlinear dynamical systems. In his prize-winning work (1889), Poincaré discusses mainly the restricted three-body problem, where one mass is negligible

compared with the other two, executing circular Keplerian motion.

Within the three-dimensional constant-energy manifold of this problem, he considered a two-dimensional surface Π transversal to most of the orbits. An orbit starting on this surface at a point x will pierce it again for the first time at some point y . The map $x \rightarrow y$ is the Poincaré return map induced on a surface of section Π .

It was in this framework that he discovered the existence of homoclinic orbits, that is, orbits which are asymptotically attracted by some periodic orbit γ when $t \rightarrow +\infty$ and $t \rightarrow -\infty$.

During his 1912 investigations on the restricted three-body problem, Poincaré conjectured that if one has a closed plane annulus Ω bordered by two concentric circles Γ_1 and Γ_2 , then any area-preserving homeomorphism ϕ of Ω , such that $\phi(\Gamma_1) = \Gamma_1$, $\phi(\Gamma_2) = \Gamma_2$ and rotating these circles in opposite directions, has in Ω at least two different fixed points. This assertion, known as Poincaré's last geometric theorem, was proved in 1913 by George D. Birkhoff and is known also as the Poincaré–Birkhoff theorem.

Inspired by the analogy between a flow induced by a vector field and a flow of an incompressible fluid, Poincaré developed a theory of integral invariants, which was later refined by Elie Cartan.

Considering time t as an independent variable, we can study Hamiltonian system (2) in the extended phase space (q, p, t) . A tube of trajectories is a two-dimensional cylindrical surface formed by the segments of trajectories of the vector field defined by (2) and bounded by two disjoint smooth closed curves. According to the Poincaré–Cartan theorem, in the extended phase space (q, p, t) , the action integral $\int_{\gamma} (p dq - H dt)$ has the same value for two different closed paths γ_1 and γ_2 encircling the same tube of trajectories and lying on it.

Poincaré also proved an important property of the long-time behavior of dynamical systems. In contemporary formulation, this proof shows that for any measure-preserving mapping of a measure space with a finite total measure, almost all trajectories starting from a given subset of positive measure eventually return to it. This is known as the Poincaré recurrence theorem, and it lies at the foundations of ergodic theory.

In his works on celestial mechanics, Poincaré provided the first formal definition of asymptotic series: divergent series giving nevertheless good numerical approximations for functions they represent.

Poincaré is the founder of the concept of normal forms in the theory of ordinary differential equations and of the contemporary bifurcation theory. His work was also at the beginning of modern variational methods in mathematics, in particular of the Morse theory which strongly links mathematical analysis to geometry and topology.

Other nonlinear problems studied by Poincaré include the problem of the existence of geodesics on convex surfaces, the problem of tides, and the stability of rotating fluid bodies.

Poincaré's impact on the theory of ordinary differential equations and dynamical systems is described in the books by Birkhoff (1927), Nemytskii & Stepanov (1960), Coddington & Levinson (1955), and Guckenheimer & Holmes (1990).

POINCARÉ–BENDIXSON THEOREM

See Phase plane

POISSON BRACKETS

Let M be an n -dimensional manifold (referred to as the phase space), and let f , g , and h denote analytic functions on M . A Poisson bracket of any two analytic functions on the phase space is defined as an operation which satisfies

- (i) $\{\alpha f + \beta g, h\} = \alpha\{f, h\} + \beta\{g, h\}$, (linearity in the first component);
- (ii) $\{f, g\} = -\{g, f\}$ (skew-symmetry);
- (iii) $\{f, \{g, h\}\} + \{g, \{h, f\}\} + \{h, \{f, g\}\} = 0$ (Jacobi identity);
- (iv) $\{f, gh\} = g\{f, h\} + \{f, g\}h$ (Leibniz property),

where α, β are numbers. The first two properties ensure that a Poisson bracket is a bilinear operation on M . Properties (i)–(iii) imply that the analytic functions on M form a Lie algebra with respect to the Poisson bracket.

If local coordinates z_i , $i = 1, \dots, n$ are chosen on M , then the Poisson bracket has the coordinate representation

$$\{f, g\} = \sum_{j,k=1}^n J_{jk}(z) \frac{\partial f}{\partial z_j} \frac{\partial g}{\partial z_k} = (\nabla f)^T \mathbf{J} \nabla g, \quad (1)$$

where $\nabla f = (\partial f / \partial z_1, \dots, \partial f / \partial z_n)$, and the Poisson matrix $\mathbf{J}(z) = (J_{jk}(z))_{j,k=1}^n$ is a skewsymmetric square matrix, satisfying a technical condition enforced by the Jacobi identity.

Any nonconstant function C on M that Poisson commutes with all other functions on M is called a Casimir of the Poisson bracket. From (1) it follows that the existence of a Casimir requires $\mathbf{J}$ to be singular, and ∇C is in the null space of $\mathbf{J}$. Furthermore, the number of independent Casimirs is the corank of $\mathbf{J}$. For a Poisson bracket with r Casimirs $C_1, \dots, C_r$, Darboux's theorem states that it is always possible to find coordinates $(q_1, \dots, q_N, p_1, \dots, p_N, C_1, \dots, C_r)$ on M such that in these coordinates

$$\mathbf{J} = \begin{pmatrix} \mathbf{0} & \mathbf{I}_N & \mathbf{0} \\ -\mathbf{I}_N & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} \end{pmatrix}, \quad (2)$$

where $\mathbf{I}_N$ is the N -dimensional identity matrix, and $\mathbf{0}$ is the zero matrix of the appropriate dimensions. In these coordinates,

$$\{f, g\} = \sum_{j=1}^N \left(\frac{\partial f}{\partial q_j} \frac{\partial g}{\partial p_j} - \frac{\partial f}{\partial p_j} \frac{\partial g}{\partial q_j} \right). \quad (3)$$

This representation of the Poisson bracket is called the canonical Poisson bracket, and the coordinates $(q_1, \dots, q_n, p_1, \dots, p_n)$ are called canonical coordinates.

The importance of Poisson brackets is derived from their relationship to Hamiltonian systems: let H be a function on M . Hamiltonian dynamics with Hamiltonian function H are defined on any function f on M by

$$\dot{f} = \{f, H\}. \quad (4)$$

Using the coordinate representation (1), the Hamiltonian dynamics for the coordinates is

$$\dot{z}_j = \{z_j, H\} = \sum_{k=1}^n J_{jk} \frac{\partial H}{\partial z_k}, \quad (5)$$

which reduces to the standard definition of a Hamiltonian system if canonical coordinates are used. From (4) it is clear that any function that Poisson commutes with the Hamiltonian is conserved for the Hamiltonian system defined by the Poisson bracket and the Hamiltonian H . In particular, H is conserved. Also, any Casimir is conserved. Because the conservation of the Casimirs is independent of the choice of H , they do not contain dynamical information. Rather, as is obvious from Darboux's theorem, they foliate the phase space and represent geometric restrictions on the possible motions in phase space. A Hamiltonian system can also be defined using the Hamiltonian function H and a symplectic two-form, of which $\mathbf{J}^{-1}$ (if it exists) is the coordinate representation (Weinstein, 1984).

As an example, consider Euler's equations of a free rigid body (Weinstein, 1984). Denote the angular momentum by (M_1, M_2, M_3) and the moments of inertia by I_1, I_2, I_3 . The Poisson matrix is

$$\mathbf{J} = \begin{pmatrix} 0 & M_3 & -M_2 \\ -M_3 & 0 & M_1 \\ M_2 & -M_1 & 0 \end{pmatrix}. \quad (6)$$

The Hamiltonian is $H = (M_1^2 / I_1 + M_2^2 / I_2 + M_3^2 / I_3) / 2$. The Poisson matrix has rank 2 (except at the origin), and there is one Casimir: $C_1 = M_1^2 + M_2^2 + M_3^2$.

The notion of Poisson brackets extends to infinite-dimensional phase spaces, so as to describe dynamics governed by evolution (partial differential) equations (Marsden & Morrison, 1984). In this case, the Poisson matrix $\mathbf{J}$ is replaced by a skew-adjoint differential operator B . If the evolution equation is first order in the dynamical variable t , this operator is scalar. Otherwise it is a matrix operator of the same dimension as the order of the evolution equation. Instead of functions on phase space, we consider functionals

$$F[\mathbf{u}] = \int f[\mathbf{u}] dx. \quad (7)$$

Here $\mathbf{u}(x, t)$ is an infinite-dimensional coordinate on the phase space, indexed by the independent variable x . The square brackets denote that $f[\mathbf{u}]$ depends not only on $\mathbf{u}$, but possibly also on its derivatives with respect to x : $\mathbf{u}_x, \mathbf{u}_{xx}, \dots$. The limits of integration depend on the boundary conditions imposed on the evolution equation. In the above, the variable x is assumed to be one dimensional. This is extended to higher dimensions in obvious fashion.

The Poisson bracket between any two functionals on phase space is the functional given by

$$\{F, G\} = \int \frac{\delta F}{\delta \mathbf{u}} B \frac{\delta G}{\delta \mathbf{u}} dx, \quad (8)$$

where $\delta F / \delta u$ is the variational (or Fréchet) derivative of F with respect to u :

$$\frac{\delta F}{\delta u} = \frac{\partial f}{\partial u} - \frac{\partial}{\partial x} \frac{\partial f}{\partial u_x} + \frac{\partial^2}{\partial x^2} \frac{\partial f}{\partial u_{xx}} - \dots \quad (9)$$

The Poisson bracket defined this way satisfies properties (i), (ii), and (iv). The operator B is chosen so that the Jacobi identity (iii) is also satisfied.

A functional H on the phase space defines Hamiltonian dynamics on any functional by

$$\frac{\partial F}{\partial t} = \{F, H\} \Leftrightarrow \frac{\partial u}{\partial t} = \{u, H\} = B \frac{\delta H}{\delta u}. \quad (10)$$

As an example, consider the Korteweg–de Vries equation $u_t = uu_x + u_{xxx}$ (Gardner, 1971; Zakharov & Faddeev, 1971). This equation with $-\infty < x < \infty$ is Hamiltonian with $B = \partial/\partial x$ and $H = \int_{-\infty}^{\infty} (u^3/6 - u_x^2/2) dx$. Thus, the Poisson bracket is

$$\{F, G\} = \int_{-\infty}^{\infty} \frac{\delta F}{\delta u} \frac{\partial}{\partial x} \frac{\delta G}{\delta u} dx, \quad (11)$$

and $\int_{-\infty}^{\infty} u dx$ is its only Casimir.

The Poisson bracket formulation of a Hamiltonian system is especially significant when a quantum description of the dynamics is required. Dirac's principle of canonical quantization postulates that such a quantum description is obtained by replacing all classical quantities by their quantum mechanical operator counterparts (generalized coordinates $q \rightarrow \hat{q}$, the operation of multiplying by q , momentum $p \rightarrow -i\hbar\partial/\partial q$, etc., and all Poisson brackets by commutators/ $(i\hbar)$). Then, in the classical limit as $\hbar \rightarrow 0$, the quantum mechanical equations reduce to classical equations, as desired by the correspondence principle.

Poisson brackets were introduced by Siméon-Denis Poisson (1809) during his investigations on perturbation theory in classical mechanics. Poisson's *Traité de mécanique* (two volumes, 1811 & 1833) were standard texts for many years.

POLARITONS

A simple view of a dielectric material is that it is just an insulator made from atoms that have bound positive and negative charges. The ratio of an electric field measured in vacuum to that measured inside a dielectric material is called the dielectric constant. The opposite signs of the charges make the atoms electrically neutral, but these charges can be pulled apart by an applied electric field and they are displaced in opposite directions. If this happens, the material is said to be polarized. A metal, on the other hand, appears to be more complicated; it is a conductor and a solid-state plasma. Often called the fourth state of matter, a plasma is an electrically neutral assembly of separated electrons and positively charged ions. A metal is precisely like this but, unlike a gaseous plasma, it has a highly mobile “sea” of electrons carrying charges that are exactly balanced by a virtually immobile set of positive charges residing on the ionic background making up the crystal lattice. The same can be said for a heavily doped semiconductor. In spite of the plasma nature of a metal, its interaction with electromagnetic waves is well modeled by a dielectric function that turns out to be frequency-dependent (Kittel, 1995).

To understand the physical interaction between an electromagnetic wave and a dielectric, it is instructive to look at a (deceptively) simple model of how electrons behave in a metal or a heavily doped semiconductor when exposed to an electromagnetic wave. The core, realistic assumption in this model is that the electrons are highly mobile and free to move against an immobile ionic background. Suppose that the electric field carried by the electromagnetic wave is $\mathbf{E} = (0, 0, E)$, with a time variation $e^{i\omega t}$, where ω is an angular frequency. For a free electron with mass m , charge $-e$, and velocity v , moving in one dimension, the equation of motion becomes

$$i\omega m v = -eE. \quad (1)$$

If N is the number density of the electrons, this particle motion creates a current density with a magnitude j ,

$$j = -Ne v = i \left(\frac{Ne^2}{\omega m} \right) E = i\omega P, \quad (2)$$

where P is called the polarization. The latter should be thought of as being excited as a dipole moment per unit volume by the electromagnetic wave. Defining the electric displacement vector of free space as D , and the

magnetic field as $\mathbf{H}$, the appropriate Maxwell equation to incorporate (2) is

$$\begin{aligned}\text{curl } \mathbf{E} &= \frac{\partial \mathbf{D}}{\partial t} + \mathbf{j} = i\omega\epsilon_0 \mathbf{E} - i\frac{Ne^2}{\omega m} \mathbf{E} \\ &= i\omega\epsilon_0 \left[1 - \frac{\omega_p^2}{\omega^2} \right] \mathbf{E}\end{aligned}\quad (3)$$

in which t is time and ϵ_0 is the permittivity of free space. Equation (3) shows that a metal is neatly modeled by the frequency-dependent relative permittivity

$$\epsilon(\omega) = 1 - \frac{\omega_p^2}{\omega^2}, \quad (4)$$

where $\omega_p^2 = \left(\sqrt{Ne^2/\epsilon_0 m} \right)^2$ is called the plasma frequency. For this to also be a useful description of a semiconductor, or to take into account that the ionic background of a metal may contribute a frequency-independent permittivity, all that is necessary is to replace unity in Equation (4) with a quantity ϵ_L , which can be much greater than unity for semiconductors. This model gives good agreement with experiment, and it also serves to introduce the polariton concept. Excitations other than those of a free-electron gas are easy to capture, once this basic example is accepted. In a one-dimensional system stretching along the x -axis, the electrons move a distance $x = e\mathbf{E}/(\omega^2 m)$ and the polarization is $\mathbf{P} = -Ne\mathbf{x}$.

If a plane electromagnetic wave has a wave vector $\mathbf{k}$ and (4) is the dielectric function, then

$$\begin{aligned}\mathbf{k} \times \mathbf{E} &= \omega\mu_0 \mathbf{H}, \\ \mathbf{k} \times \mathbf{H} &= -\omega\epsilon_0 \epsilon(\omega) \mathbf{E},\end{aligned}\quad (5)$$

where μ_0 is the magnetic permeability of free space. As a specific example, let the propagation be along the x -axis with wave vector $\mathbf{k} = (k, 0, 0)$ and let the electric field vector be $\mathbf{E} = (E_x, 0, E_z)$. The following modes are then implied (Boardman, 1982) by (5):

$$\text{Transverse : } (\omega^2 - \omega_p^2 - c^2 k^2) E_z = 0, \quad (6)$$

$$\text{Longitudinal : } (\omega^2 - \omega_p^2) E_x = 0, \quad (7)$$

where $c^2 = 1/(\epsilon_0 \mu_0)$ is the velocity of light in vacuum and there are two independent solutions. The longitudinal mode is sustained when $E_x \neq 0$ and $\omega = \omega_p$. For this mode, the electrons move collectively in an oscillation that resembles the wobbling of a jelly.

At this stage, it should be pointed out that physicists are prone to call things by “ons” (Walker & Slack, 1970). All this started with the word *electron*. Unfortunately, the latter word does not, in itself, explain too much about the “on” part of the word, which is derived from the Greek word for “amber”—a fact that Benjamin Franklin would readily appreciate. Nevertheless, the electron is recognized to have a particle nature so

physicists have become used to defining an “on” in association with an excited field, such as an electromagnetic wave or the jelly-like plasma oscillation. Thus, a *photon* is a particle, or quantum of energy, of light and the quantum of the wobbling electronic jelly, or plasma oscillation, is called the *plasmon*. The name *polariton* (Hopfield, 1958) is reserved for the quantum of an excitation in which electromagnetic waves cannot disentangle themselves from excitations such as plasmons.

The coupling of an electromagnetic field to the polarization excitations associated with electrons can be seen from the transverse solution (6). This shows that a finite value for E_z requires the dispersion equation to be

$$\omega^2 = \omega_p^2 + c^2 k^2 \quad (8)$$

Furthermore, this equation shows that the excitation is mixed because it involves not only the plasma frequency but also the velocity of light. It is for this reason that the quantum of this photon-plasmon field is called a polariton, as indicated earlier. The total energy is shared over the system because the mode has both plasmon and photon content, as can be seen by looking at the low and high wave number limits of (8). As $\mathbf{k} \rightarrow 0$, the frequency tends towards the plasma frequency, and the plasmon content grows at the expense of the photon contribution. The opposite is true as $\mathbf{k} \rightarrow \infty$, and the wave becomes a pure electromagnetic wave. The “on” labeling is not complete, however, unless the type of polariton is identified, so, in this case, they are referred to as plasmon-polaritons. This labeling is a reminder that only plasmons have been used here to introduce the concept of polaritons. The description is generic, however, and there are many types of polaritons. All that is necessary to generalize the discussion given here is to decide which polarization excitation the photons couple with and capture the material polarization properties through an effective permittivity. Well-known examples involve plasmons, excitons, and phonons.

After several decades of research, polaritons are still attracting attention (Baher & Cottam, 2003), in both guided and surface wave form, and the study of nonlinear polaritons in particular has opened new horizons (Boardman & Egan, 1985). The inclusion of nonlinearity means extending the permittivity to depend upon the amplitude of the electromagnetic wave through a functional dependence upon E , such as

$$\epsilon(\omega, E) = \epsilon(\omega) + \epsilon^{\text{NL}}(|E|) \quad (9)$$

Here $\epsilon(\omega)$ is the relative permittivity for the excitation of choice, such as phonons, plasmons, or excitons. To reduce (9) to a tractable form, a Kerr-type of optical nonlinearity can be adopted, in which the total permittivity is expressed as

$$\epsilon(\omega, E) = \epsilon(\omega) + a|E|^2, \quad (10)$$

where a is a nonlinear coefficient.

This type of nonlinear process is not only popular in the literature but is genuinely applicable when the nonlinearity is well away from resonance and saturation. Immediately an interesting feature appears because the form of (10) permits an investigation of the kind of transverse electric (TE) waves that have no linear ($a \rightarrow 0$) limit. This dramatic conclusion culminates in the generation of an entirely new type of polariton. The TE waves can be guided or surface waves and for this discussion are assumed to be traveling along the x -axis. The field components are, therefore,

$$\begin{aligned} \mathbf{E} &= [0, E_y(k, \omega, z), 0]e^{i(kx - \omega t)}, \\ \mathbf{H} &= [H_x(k, \omega, z), 0, H_z(k, \omega, z)]e^{i(kx - \omega t)}. \end{aligned} \quad (11)$$

Substituting (11) into Maxwell's equations produces the following equations (Boardman et al., 1991):

$$\begin{aligned} \frac{d}{dz} E_y(k, \omega, z) &= -i\omega\mu_0 H_x(k, \omega, z), \\ k E_y(k, \omega, z) &= \omega\mu_0 H_z(k, \omega, z), \\ \frac{d}{dz} H_z(k, \omega, z) &= ik H_x(k, \omega, z) \\ &\quad + i\omega\epsilon_0 \epsilon(\omega) |E_y|^2 E_y(k, \omega, z). \end{aligned} \quad (12)$$

In general, E_y is complex so that $E_y = E(k, \omega, z)e^{i\phi(k, \omega, z)}$. Using $E \equiv E(k, \omega, z)$, $\phi \equiv \phi(k, \omega, z)$, and $\epsilon \equiv \epsilon(\omega)$ in (12) produces the following basic nonlinear equations:

$$\begin{aligned} \frac{d^2}{dz^2} E - E \left(\frac{d\phi}{dz} \right)^2 + \left(\frac{\omega^2}{c^2} \epsilon - k^2 \right) E + \frac{\omega^2}{c^2} a E^2 &= 0, \\ \frac{d\phi}{dz} &= \frac{K}{E^3}. \end{aligned} \quad (13)$$

The last equation expresses the conservation of energy flux along the z -axis, which is perpendicular to the propagation direction, and K is a constant of the integration process. The z -component of the time-averaged Poynting vector is

$$\langle S \rangle_z = -\frac{1}{2} \text{Re}(E^* H_x) = \frac{c^2}{2\omega^2} \epsilon_0 K. \quad (14)$$

Hence, $K = 0$ implies $\langle S \rangle_z = 0$. Finally,

$$\left(\frac{dE}{dz} \right)^2 + \left(\frac{\omega^2}{c^2} \epsilon(\omega) - k^2 \right) E^2 + \frac{a}{2} \frac{\omega^2}{c^2} E^4 = C, \quad (15)$$

where C is another constant of integration. For a semi-infinite medium, $C = 0$, otherwise $C \neq 0$.

Consider now a $C = 0$ case describing a semi-infinite nonlinear medium interfaced to a semi-infinite linear medium. As it is well known that linear surface plasmon-polaritons are transverse magnetic (TM) polarized waves, the nonlinearity has added the extra functionality of making it possible to have TE-polarized surface plasmon-polariton waves. The field profile of

these TE nonlinear waves is readily obtained from (15), since it factorizes when $C = 0$. The solution is

$$\begin{aligned} E &= \frac{c}{\omega} \sqrt{\frac{2}{a}} \sqrt{\left(k^2 - \frac{\omega^2}{c^2} \epsilon(\omega) \right)} \\ &\quad \times \text{sech} \left[\sqrt{k^2 - \frac{\omega^2}{c^2} \epsilon(\omega)} (z - z_0) \right]. \end{aligned} \quad (16)$$

This is a self-focused (self-guided) beam that has a peak in the nonlinear medium below the interface. This nonlinear surface wave looks exactly like a spatial soliton. Furthermore, there is no linear limit for the nonlinear TE-polarized surface plasmon-polaritons. The frequency dependence for guided modes is more complex and can have a linear limit.

Polaritons are being studied in a wide variety important of contexts. Some examples include nonlinear exciton-polariton dynamics in the experimental study of semiconductor microcavities (Savvides et al., 2000), two-dimensional electron systems in quantizing magnetic fields (Beletskii & Bludov, 2002), and plasmon-polaritons in dielectric films (Baher & Cottam, 2003). The idea that underpins the polariton concept can be put to dramatic use in an unusual way. This is possible because to create polaritons, photons must associate themselves with the quanta or the quasiparticles of collective excitations, be they plasmons, phonons, or related excitations. The polariton is a genuine collaborative effect between the photons and particles that are acting in a prepared organized manner, which means that the particles are not absorbing or emitting the photons. If a stream of photons (a light beam) is sent through an atomic gas (Lukin et al., 2000), for example, then provided the gas atoms are not resonant with the laser wavelength, the atoms should swarm around the photons rather like bees around a honey pot. In other words, polaritons should be formed. Furthermore, these polaritons could be organized, through an appropriate choice of laser intensity, to travel at a speed that is much less than the velocity of light. The particle swarm that has associated itself with the photon will slow down the light dramatically. This is an elegant idea and is a striking illustration of the character of the polariton. It is not surprising that the phrase "to catch a moonbeam" has been used (Sincelli, 2000) to describe the polariton-based possibility of slowing down light to walking speed.

POLARONS

The polaron concept goes back to 1933 when Lev Landau suggested the phenomenon of self-localization (self-trapping) of an electron (or a hole), slowly moving in a polar crystal (Landau, 1933). The electron locally polarizes and, therefore, distorts the ionic lattice in the region where it is located. This local lattice distortion, in turn, creates a potential well that traps the electron, lowering its energy. Therefore, the electron and the accompanying self-consistent polarization field can move in the crystal as a whole entity and may be considered as a quasi-particle. The term *polaron* was introduced in 1946 by Solomon Pekar, who studied the limiting (adiabatic) case of a sufficiently strong electron-lattice interaction and described the most-important properties of a stationary polaron, using a continuum model of electron motion (Pekar, 1946).

Pekar's theory of a polaron is based on the assumption that the polar coupling between electrons and optical phonons can be very large in ionic crystals. In ionic crystals, some of the ions are positively charged, while others are negatively charged, and an optical phonon has the different ions in the crystal vibrating out of phase. When the positive ions and negative ions oscillate in opposite directions (at a point $\mathbf{r}$ of the crystal), they create a polarization field $\mathbf{P}(\mathbf{r})$. This causes an electric field $\mathbf{E}(\mathbf{r})$, which is the source of the polar coupling. Polar coupling is only to longitudinal optical (LO) phonons, because only LO phonons set up a strong electric field when they vibrate.

(This electric field is in the direction of the phonon wave vector $\mathbf{q}$.) Writing the expansion in normal modes:

$$\begin{aligned} \mathbf{E}(\mathbf{r}) &= N^{-1/2} \sum_{\mathbf{q}} \mathbf{E}_{\mathbf{q}} e^{i\mathbf{q}\cdot\mathbf{r}} \\ \mathbf{P}(\mathbf{r}) &= N^{-1/2} \sum_{\mathbf{q}} \mathbf{P}_{\mathbf{q}} e^{i\mathbf{q}\cdot\mathbf{r}} \end{aligned} \quad (1)$$

with N being the number of ions in the crystal and using the fact that there are no free charges, that is, $\nabla \cdot (\mathbf{E} + 4\pi\mathbf{P}) = 0$, one obtains the relation

$$\mathbf{E}_{\mathbf{q}} = -4\pi\mathbf{P}_{\mathbf{q}}. \quad (2)$$

Each $\mathbf{P}_{\mathbf{q}}$ is proportional to the (quantized) displacement field

$$\mathbf{P}_{\mathbf{q}} = U_{\mathbf{q}} e \left(\frac{\hbar}{2M\omega_{\mathbf{q}}} \right)^{1/2} i \frac{\mathbf{q}}{|\mathbf{q}|} \left(a_{\mathbf{q}}^{\dagger} + a_{-\mathbf{q}} \right), \quad (3)$$

where the coefficient $U_{\mathbf{q}}$ is to be determined, e is the electron charge, M the ion mass, $\omega_{\mathbf{q}}$ is the frequency of the $\mathbf{q}$ th mode, and $a_{\mathbf{q}}$ ($a_{\mathbf{q}}^{\dagger}$) is the annihilation (creation) operator of the $\mathbf{q}$ th mode.

On the other hand, the electric field can be represented as a gradient of a potential field:

$$\mathbf{E}(\mathbf{r}) = -\nabla\phi(\mathbf{r}) = -i \sum_{\mathbf{q}} \mathbf{q} e^{i\mathbf{q}\cdot\mathbf{r}} \phi_{\mathbf{q}}. \quad (4)$$

Using Equations (1)–(4), the potential field for the electron is

$$\begin{aligned} \phi(\mathbf{r}) &= 4\pi e \sum_{\mathbf{q}} U_{\mathbf{q}} e^{i\mathbf{q}\cdot\mathbf{r}} \left(\frac{\hbar}{2NM\omega_{\mathbf{q}}} \right)^{1/2} \\ &\quad \times \frac{1}{|\mathbf{q}|} \left(a_{\mathbf{q}}^{\dagger} + a_{-\mathbf{q}} \right). \end{aligned} \quad (5)$$

Because each normal mode $\mathbf{q}$ assumes a new equilibrium configuration and oscillates in the vicinity of these new equilibria, the coupling constant $U_{\mathbf{q}}$ can be evaluated from the potential energy between two fixed electrons. For a dispersionless polar crystal, when the frequency $\omega_{\mathbf{q}}$ is nearly a constant ($\omega_{\mathbf{q}} \doteq \omega_0$), Pekar has derived the value

$$U_0^2 = \frac{\rho\omega_0^2}{4\pi} \left(\frac{1}{\varepsilon_{\infty}} - \frac{1}{\varepsilon_0} \right), \quad (6)$$

where ρ is the mass density of the crystal (so $\rho V = NM$, with V being the crystal volume). The dielectric constants ε_0 and ε_{∞} are both measurable: ε_0 is measured by putting the crystal between the parallel plates of a capacitor at low frequency and ε_{∞} is the square of the refractive index.

Thus, it is possible to write the total Hamiltonian of a single electron that interacts with the phonons in the form

$$\begin{aligned} H &= \frac{\mathbf{p}^2}{2m} + \omega_0 \sum_{\mathbf{q}} a_{\mathbf{q}}^{\dagger} a_{\mathbf{q}} \\ &\quad + V^{-1/2} \sum_{\mathbf{q}} \frac{\chi_0}{|\mathbf{q}|} e^{i\mathbf{q}\cdot\mathbf{r}} \left(a_{\mathbf{q}}^{\dagger} + a_{-\mathbf{q}} \right). \end{aligned} \quad (7)$$

Here the unperturbed electron is taken to have free-particle motion with a momentum $\mathbf{p}$ and an effective mass m . Since there is only one electron in the problem, the results are independent of the statistics of the particle. The same results are obtained for any fermion or boson in the crystal, such as holes, excitons, or other particles, as long as they are free to move. Owing to Equations (5) and (6), the electron-phonon coupling constant χ_0 in Hamiltonian (7) is given by

$$\chi_0^2 = 4\pi\alpha\hbar(2m)^{-1/2}(\hbar\omega_0)^{3/2} \quad (8)$$

with the dimensionless polaron constant

$$\alpha = \frac{e^2}{\hbar} \left(\frac{m}{2\hbar\omega_0} \right)^{1/2} \left(\frac{1}{\epsilon_\infty} - \frac{1}{\epsilon_0} \right). \quad (9)$$

In Pekar's analysis of this model, the method of calculation is basically a variational procedure using a Gaussian wave function. The total wave function is assumed to be the product of electron and phonon coordinates (adiabatic approximation):

$$\begin{aligned} \Phi(\mathbf{r}; \mathbf{Q}_q) &= \varphi(\mathbf{r})\psi_n(\mathbf{Q}_q + \delta\mathbf{Q}_q), \\ \varphi(\mathbf{r}) &= \frac{\beta^{3/2}}{\pi^{3/4}} \exp\left(-\frac{\beta^2\mathbf{r}^2}{2}\right), \end{aligned} \quad (10)$$

where β is a variational parameter to be determined. The phonon wave functions ψ_n are the wave functions for harmonic oscillators centered about new equilibrium displacements, which also need to be determined. Having carried out the variational procedure, one obtains the minimum value of β and the total energy $E = E(\beta)$ of the coupled electron-phonon system:

$$\begin{aligned} \beta_0 &= \frac{2\alpha}{3} \sqrt{\frac{m\omega_0}{\pi}}, \\ E(\beta_0) &= -\frac{\alpha^2\omega_0}{3\pi} \simeq -0.106\alpha^2\omega_0. \end{aligned} \quad (11)$$

This result shows the existence of a dynamically stable, self-localized state of an electron interacting with optical phonons in ionic crystals and having a finite binding energy, under the condition that the size of the self-trapped state is large compared with the lattice spacing constant (so the lattice discreteness becomes irrelevant in the theory).

Pekar's continuum polaron was the first model of a self-trapped state admitting a self-consistent theoretical treatment. The importance of this problem was soon understood by many theoretical and mathematical physicists working in solid state physics and quantum field theory, including N.N. Bogolyubov, S.V. Tyablikov, T.D. Lee, H. Fröhlich, R.P. Feynman, E.I. Rashba, T. Holstein, Y. Toyozawa, I.G. Lang, and Yu.A. Firsov. As a result, several pioneering works were published in the 1950s, favoring use of the methods of quantum field

theory in solid state physics. Thus, the "polaron" concept has lost its original meaning as an electron interacting with long-wave-length polarized optical phonons and has been applied to a significantly wider class of self-trapped states, resulting in a large body of work that includes exciton-phonon interactions (Rashba, 1957) and even applications in biology (Scott, 1992), with very recent important contributions to the classical polaron theory (Romero et al., 1999). In this context, the following comments are relevant:

(i) The strong coupling limit in Pekar's theory is calculated in the adiabatic approximation, when the electron has a sufficient binding energy and its oscillatory motion in the potential well is much faster than the vibrational frequency of the phonons. Thus, the phonons do not have time to adjust to the individual oscillations of the electron. Instead, they adjust to the average motion of the electron. Quite a different picture applies to the weak coupling limit. In this case, the phonon energy is larger than that of the electron, so that the phonons (or ion polarization) follow the electron during its motion. The weak coupling limit was studied by Fröhlich within his polaron model, in which Hamiltonian (7) was generalized to (Fröhlich, 1954)

$$\begin{aligned} H &= \sum_{\mathbf{k}} \frac{k^2}{2m} c_{\mathbf{k}}^\dagger c_{\mathbf{k}} + \omega_0 \sum_{\mathbf{q}} a_{\mathbf{q}}^\dagger a_{\mathbf{q}} \\ &+ V^{-1/2} \sum_{\mathbf{q}, \mathbf{k}} \frac{\chi_0}{|\mathbf{q}|} c_{\mathbf{k}+\mathbf{q}}^\dagger c_{\mathbf{k}} (a_{\mathbf{q}}^\dagger + a_{\mathbf{q}}), \end{aligned} \quad (12)$$

where $c_{\mathbf{k}}$ ($c_{\mathbf{k}}^\dagger$) is the annihilation (creation) operator of the electron with the wave number $\mathbf{k}$. However, the most sophisticated study of the "large" (or "continuum") polaron, using the Fröhlich Hamiltonian (12), is due to Feynman (1955) with the path-integral method, substantially extended in the past decade. For an extensive review of the large polaron studies in both the strong and weak coupling limits, see Mitra et al. (1987).

(ii) When the electron-phonon coupling constant is large, all the states in the Brillouin zone are involved in the formation of the polaron wave function. In this case, the polaron radius becomes comparable with the lattice constant and the continuum approximation is no longer valid. For a "small" polaron, the theory should recognize the periodicity of the crystal and thereby assume that the motion of the electron, or another particle, is no longer translationally continuous. Therefore, one assumes that the electron may occupy an orbital state $\phi(\mathbf{r} - \mathbf{R}_j)$ centered on an atomic site $\mathbf{R}_j$. The orbital states are identical on each site, so that there is periodicity. The electron may move from site to site as in the tight-binding model. This motion may be caused by the overlap of the orbitals on adjacent

sites. Thus, the following Hamiltonian is suitable for the small polaron theory:

$$H = J \sum_{j,l} C_{j+l}^\dagger C_j + \sum_q \omega_q a_q^\dagger a_q + \sum_{j,q} \chi_q e^{iq \cdot \mathbf{R}_j} C_j^\dagger C_j \left(a_q^\dagger + a_{-q} \right), \quad (13)$$

where the factor J describes the overlap of the orbitals and C_j ($C_j^\dagger$) is the annihilation (creation) operator of the electron on site $\mathbf{R}_j$. Basic features of the small polaron were well recognized a long time ago by Tyablikov, Holstein, Lang, and Firsov, among others, and are described in several review papers and textbooks (Appel, 1968; Böttger & Bryksin, 1985; Mahan, 1990; Alexandrov & Mott, 1995).

(iii) Another interesting case is a problem of the lattice polaron with a long-range Fröhlich interaction. This polaron has a small (atomic) size of wave function but a large radius of lattice deformation. As shown recently (Alexandrov & Kornilovitch, 1999), this “small Fröhlich polaron” can propagate in a narrow band with the effective mass much smaller than that of the Holstein small polaron of the same binding energy. Alexandrov and Kornilovitch argue that small as well as large Fröhlich (bi)polarens are relevant quasiparticles in the cuprates, describing holes in the CuO_2 plane coupled with the lattice distortion created by a long-range interaction.

(iv) The polaron concept appeared so ubiquitous that it was used even in biology to describe a possible mechanism of the localization and transport of vibrational energy in molecular chains, particularly in proteins. As was suggested by Davydov, the energy of the C=O stretching (amide-I) vibrations, being localized on a peptide group of the α -helix, distorts the structure of the helix in this place. In its turn, a (contractive) distortion of the helical chain creates a potential well that traps the amide-I oscillation energy preventing its dispersion. This mobile self-localized (or self-trapped) state that can travel along the chain, carrying the energy released under the adenosine triphosphate (ATP) hydrolysis, is called a “Davydov soliton” (Scott, 1992).

POLYMERIZATION

Polymers are long molecules made from one or more types of repeating units, called monomers. The simplest synthetic polymer consists of hundreds to even millions of monomers that are connected end to end in a linear chain. Polymers are essential to our modern world and our very life. Biochemical systems involve polymers because all enzymes are proteins, a type of polymer composed of about 20 different amino acids. DNA and RNA are also polymers but formed from four different bases (Nelson & Cox, 2000). Goldbeter (1995) discusses well the type of nonlinear phenomena that can occur. We focus only on synthetic polymers here.

A distribution of chain lengths always exists in a synthetic system. This molecular weight distribution can be quite broad, often spanning several orders of magnitude. However, biopolymers consist of a single molecular weight.

Linear polymers are often thermoplastic, meaning that they can flow at some temperature, which depends on the molecular weight. Common examples are poly(styrene) and poly(methyl methacrylate), whose trade name is Plexiglass.

Polymers need not be simple chains but can be branched or networked. Linear polymers are analogous to strings of spaghetti. Crosslinked polymers can be gels that swell in a solvent or thermosets, which form rigid three-dimensional networks. Home epoxy glue is an example of a crosslinked polymer. Figure 1 illustrates these variations.

Figure 1. Illustration of three types of polymers: (a) linear, (b) branched, (c) crosslinked.

Polymer Kinetics and Mechanisms of Feedback

The mechanism of polymerization usually falls into one of two categories: chain growth or step growth. In chain-growth polymerization, a monomer is converted into a reactive species by an initiating species, either an ion or a free radical (a molecule containing an unpaired electron), that rapidly reacts with other monomers while always maintaining the reactive character. The reactive chain can be broken through some termination process. In most cases, even though relatively little of the monomer has reacted, high molecular weight molecules are produced in a few seconds. They usually do not participate further in the reaction. Plexiglass is produced via free-radical chain-growth polymerization.

For step-growth polymers, the monomers can usually react from both ends, and thus, all the monomers and polymers can react with each at any time from both ends. The molecular weight increases continuously throughout the reaction as monomers react to form dimers, and then dimers can react with each other or monomers, etc.

The physical properties of the polymer medium change dramatically during reaction. For example, the viscosity almost always increases orders of magnitude as the polymer concentration and/or molecular weight increases. This can be understood if you consider stirring a pot of penne versus a pot of spaghetti: the longer pasta pieces intertwine and resist flowing. Such physical changes will often affect the kinetic parameters of the reaction and the transport coefficients of the medium.

Synthetic polymer systems can exhibit feedback through several mechanisms. The simplest is thermal autocatalysis, which occurs in any exothermic reaction. The reaction raises the temperature of the system, which increases the rate of reaction through the Arrhenius dependence of the rate constants. Most chain-growth polymerizations, including free-radical polymerizations, are highly exothermic. Some step-growth polymerizations are highly exothermic (epoxies), but some are not (polyesters).

Free-radical polymerizations of certain monomers exhibit autoacceleration at high conversion via an additional mechanism, the isothermal “gel effect” or

“Trommsdorff effect” (Odian, 1991). These reactions occur by the creation of a radical that attacks an unsaturated monomer, converting it to a radical, which can bond to another monomer, propagating the chain. The chain growth terminates when two radical chains ends encounter each other, forming a stable chemical bond. As the polymerization proceeds, the viscosity increases. The diffusion-limited termination reactions are thereby slowed down, leading to an increase in the overall polymerization rate. The increase in the polymerization rate induced by the increase in viscosity builds a positive feedback loop into the polymerizing system.

Some polymer hydrogels exhibit “phase transitions” as the pH and/or temperature are varied. Disposable diapers contain hydrogels that absorb great amounts of water because the polymers contain charged groups that bind the water. These charged groups can be affected by acid or base and are also temperature sensitive. The gel can swell significantly as the conditions are changed and can also exhibit hysteresis (Addad, 1996). Most polymers are immiscible, meaning that they will not dissolve with each other but will separate into different phases like oil and water. Introducing chemical reactions to an initially miscible polymer mixture often leads to phase separation. Autocatalytic behavior driven by chemical reactions and concentration fluctuations in miscible polymer mixtures can occur in photo-crosslinked polymer mixtures (Pojman & Tran-Cong-Miyata, 2003, Chapter 22). Concentration fluctuations increase as the reaction proceeds, leading to the reaction of photoreactive groups attached to one of the polymer components. This leads to an increase in the reaction yield that, in turn, accelerates the concentration fluctuations.

Finally, the polymer melts and the solutions are usually non-Newtonian fluids (Gupta, 2000), which means that there is no linear relationship between the stress applied to the fluid and strain that is measured. They often exhibit shear thinning, which means that the viscosity decreases as the shear is increased, but can also exhibit shear thickening. These properties make polymer additives important in the food and cosmetic industry.

Applications

There are two main scenarios by which nonlinear phenomena of possible utility arise with polymers. The first approach is to use a nonlinear system to drive the nonlinear behavior of a polymer or polymerization. Acrylonitrile will polymerize periodically when added to the Belousov–Zhabotinsky (BZ) reaction (Washington et al., 1999).

Yoshida et al. created a self-oscillating gel by coupling a pH oscillating reaction with a polymeric gel that expands and contracts with changes in pH (Yoshida et al., 1995). They have also used a gel in which the

ruthenium catalyst of the BZ reaction is chemically incorporated into polymer, causing local swelling and deswelling as chemical waves pass through the gel (Pojman & Tran-Cong-Miyata, 2003, Chapter 3).

The second approach is to use the inherent nonlinearities in a polymeric system. Polymerizations in a continuously stirred flow tank reactor (CSTR) can show nonlinear phenomena through the interaction of thermal feedback and the gel effect. Teymour and Ray showed in laboratory-scale CSTR experiments on vinyl acetate polymerization that oscillations with periods of 200 min could occur (Teymour & Ray, 1992). The gel effect causes the rate of polymerization to increase, but the increase in temperature lowers the viscosity, returning the polymerization to its lower rate.

Frontal Polymerization

One of the most promising applications of nonlinear dynamics to polymer science is the phenomenon of frontal polymerization. Frontal polymerization is a process of converting monomers into a polymer via a localized reaction zone that propagates through the monomer, much like a "liquid flame."

Thermal frontal polymerization involves the coupling of thermal diffusion and Arrhenius reaction kinetics of an exothermic polymerization (Pojman et al., 1996). Front temperatures are typically 200°C, and front velocities are from 1–20 cm/min. Because of the large composition and thermal gradients created in the front, convection can be a significant issue (Pojman et al., 1996). Simple convection can occur for thermosets in ascending fronts, but for thermoplastics, the Rayleigh–Taylor instability is a significant issue unless a filler is added to increase the viscosity.

Such systems exhibit many modes of nonplanar front propagation. Particularly fascinating are the spin modes in which the front propagates as a helix, and hot spots can be seen on the surface with an infrared camera (Figure 2). Even more complicated modes can be observed depending on the chemical composition.

Figure 2. Infrared image of a spin mode in the free-radical-frontal polymerization of an acrylate in a 1.5 cm diameter tube. (Image courtesy of J. Pojman.)

Isothermal frontal polymerization (IFP), also called interfacial gel polymerization, is a slow process in which polymerization occurs at a constant temperature and a localized reaction zone propagates because of the gel effect (Epstein & Pojman, 1998, Chapter 11). Using IFP, one can control the gradient of an added material to generate materials for optical applications.

POPULATION DYNAMICS

Biological populations have a propensity for exponential growth. This Malthusian principle is expressed by the linear, ordinary differential equation $dn/dt = rn$, $r > 0$, where $n = n(t)$ is a measure of population size or density (e.g., individual numbers, biomass, or dry weight) as a function of time t . Although populations can, under appropriate conditions, exhibit exponential growth over a finite period of time, no population can grow indefinitely according to this law. The field of nonlinear population dynamics involves the study of how

population numbers are regulated by biological and environmental effects. The equation

$$\frac{dn}{dt} = rn(1 - n/K) \quad (1)$$

is an example of a modification of the exponential growth equation. It is based on the assumption that per capita growth is a decreasing, linear function of population size. In the 1920s, many researchers, including Alfred J. Lotka, Lowell J. Reed, and, most notably, Raymond Pearl, considered Equation (1) as a fundamental law of population growth. It was later discovered that a Belgian mathematician, Pierre-François Verhulst, had used the equation in his studies of population growth in the 1840s. Equation (1) is called the Pearl-Reed equation, the Pearl-Verhulst equation, or more commonly, the "logistic equation" (a name adapted from Verhulst's name *logistique* for the equation).

Equation (1) implies all population densities monotonically approach the equilibrium K , called the carrying capacity. Before leveling off at this carrying capacity, low population numbers initially grow exponentially at the inherent growth rate r , and the resulting S-shaped trajectory is called a logistic growth curve. In their studies of human population dynamics, Pearl and his colleagues fit logistic curves to census numbers from many countries and states. Although today considered rather simplistic as a model of population growth, the logistic equation nonetheless encapsulates the notion of density self-regulation in population dynamics and has inspired many basic notions in ecology (e.g., habitat carrying capacity, the classification of species as " r or K selectors").

The logistic equation is a first-order differential equation of the Kolmogorov type

$$\frac{dn}{dt} = nf(n) \quad (2)$$

with per capita growth rate $f(n) = r(1 - n/K)$. Many theories of population growth use the Kolmogorov equations with other specialized forms for $f(n)$. One notable class of models arises from a modification of the negative feedback density regulation assumption of the logistic Equation (1) to include a positive feedback at low population numbers. This notion was put forth by W.C. Allee in order to account for increased growth rates associated with increased population size experienced by some (many biologists would say most) populations when at low numbers (although a negative feedback still comes into play at high numbers). An example is the equation

$$\frac{dn}{dt} = rn \left(1 - \frac{n}{K}\right) (n - \alpha K), \quad \alpha < 1.$$

The "Allee effect" entails a threshold αK such that populations go extinct unless their initial state $n(0)$

exceeds αK , in which case they equilibrate at the carrying capacity K .

Ordinary differential equation models based on equations of form (2) neglect important factors affecting the dynamics of real biological populations. Examples include temporal inhomogeneity (nonconstant vital rates and environment fluctuations), spatial inhomogeneity (diffusion and dispersal), and population inhomogeneity (differences among individuals). The inclusion of temporal inhomogeneities in Equation (2) produces a non-autonomous differential equation with $f = f(t, n)$. For example, a periodic carrying capacity K in the logistic Equation (1) reflects a seasonal habitat.

The movement of populations in a spatially extended habitat can be modeled by adding a diffusion or dispersal term to a growth model. For example, Fisher's equation

$$\frac{dn}{dt} = c\Delta n + rn(1 - n/K)$$

has been used to study the spread of populations by means of traveling waves. Other types of diffusion operators, including integral operators described by dispersal kernels, are often considered more appropriate for the movement of biological populations (Murray, 2003).

Differences in chronological age, body size, and other physiological characteristics of individual organisms can significantly affect birth and death rates and consequently, the entire population's dynamics. The McKendrick equation

$$\frac{\partial \rho}{\partial t} + \frac{\partial \rho}{\partial a} = -\delta \rho$$

describes the death processes of a population in terms of an age-specific density $\rho = \rho(t, a)$ and death rate δ . This equation is accompanied by a renewal or birth equation

$$\rho(t, 0) = \int \beta \rho da.$$

If the age-specific birth and death rates β and δ are independent of population density ρ , then these equations are linear and imply (under suitable conditions) the Fundamental Theorem of Demography. This theorem states that regardless of whether the population grows or decays exponentially, the normalized density approaches the positive, normalized eigensolution associated with the dominant eigenvalue. If β and/or δ are dependent on ρ , then the McKendrick model is nonlinear. This model can be used to study the effects that various life-cycle characteristics have on population level dynamics, effects such as maturation delays, gestation periods, and nonreproductive quiescent stages (Webb, 1985; Metz & Diekmann, 1986; Cushing, 1998).

Populations are often modeled using discrete time maps in which population numbers are predicted

from one census time to the next. The discrete time exponential growth is described by the linear map (or difference equation) $x_{t+1} = \lambda x_t$, $\lambda > 1$. An analog of logistic equation for density regulated growth is the Beverton–Holt equation

$$x_{t+1} = \lambda x_t \frac{1}{1 + (\lambda - 1)x_t/K},$$

whose solutions monotonically approach K as $t \rightarrow +\infty$. Other types of density-dependent, population growth models can lead to non-equilibrium asymptotic states. For example, in the Ricker model

$$x_{t+1} = \lambda x_t \exp(-cx_t),$$

larger population numbers, of sufficient magnitude, produce smaller population numbers at the next census. This type of density-dependent “depensation” produces a period-doubling, bifurcation route to chaos as the inherent growth rate λ increases. In the 1970s, Robert May stimulated the interest in complex and chaotic dynamics that flowered during the last decades of the 20th century by his studies of the Ricker model and similar one-dimensional maps as models of population growth (May, 1974).

There is a long tradition of using discrete time models to model structured populations (Caswell, 2001). The Leslie matrix model

$$\mathbf{x}_{t+1} = L\mathbf{x}_t \quad (3)$$

is an example. The components of the vector $\mathbf{x}_t$ are the number of individuals, at time t , in a finite collection of age classes. The nonnegative “projection” matrix L contains birth and survival rates per unit time. In other models, the structuring classes are based on other categories (such as body size and life cycle stage). If L is a constant in time, matrix model (3) implies (under suitable mathematical conditions) the Fundamental Theorem of Demography. If the entries of L depend on $\mathbf{x}_t$, then the model is nonlinear. Nonlinear matrix models can be used to study the effects of class specific density effects on birth and death rates. For example, a model of a population with three life cycle stages and Ricker-type negative feedback nonlinearities has been used in conjunction experimental studies to document the occurrence of a bifurcation route to chaos in a laboratory population of insects (Cushing et al., 2002).

Most populations interact with other populations in ways that affect each other’s vital rates. A natural extension of the logistic equation to the interaction of two species’ assumes per capita growth rates are linear expressions of species densities, an assumption that results in the Volterra–Lotka system

$$\begin{aligned} \frac{dn_1}{dt} &= n_1 (r_1 + c_{11}n_1 + c_{12}n_2), \\ \frac{dn_2}{dt} &= n_2 (r_2 + c_{21}n_1 + c_{22}n_2) \end{aligned}$$

of differential equations. A fundamental classification of two species’ interactions can be based on the signs of the six coefficients in these equations. Two classical examples are

$$\begin{aligned} \frac{dn_1}{dt} &= rn_1 (1 - n_1/K) - c_1 n_1 n_2, \\ \frac{dn_2}{dt} &= -dn_2 + c_2 n_1 n_2 \end{aligned} \quad (4)$$

and

$$\begin{aligned} \frac{dn_1}{dt} &= r_1 n_1 (1 - n_1/K_1) - c_1 n_1 n_2, \\ \frac{dn_2}{dt} &= r_2 n_2 (1 - n_2/K_2) - c_2 n_1 n_2. \end{aligned} \quad (5)$$

The Lotka–Volterra predator-prey model (4) describes a logistically growing prey population n_1 that is preyed upon by a predator n_2 that dies out exponentially in the absence of n_1 . In this model, the per predator uptake rate of prey is proportional to the amount of prey present, a mass-action type interaction that gives rise to the quadratic nonlinearity in (4). If $K < d/c_2$, this predator-prey model predicts predator extinction; if $K > d/c_2$, the model predicts coexistence (in terms of an asymptotically stable equilibrium state). The mass-action assumption is often replaced by one based on a predation rate that saturates (or even decreases) as the amount of prey increases. For example, the MacArthur–Rosenzweig predator-prey model,

$$\begin{aligned} \frac{dn_1}{dt} &= rn_1 (1 - n_1/K) - c_1 \frac{n_1}{a + n_1} n_2, \\ \frac{dn_2}{dt} &= -dn_2 + \frac{1}{a} c_1 \frac{n_1}{a + n_1} n_2, \end{aligned}$$

assumes a per predator prey uptake rate $c_1 n_1 / (a + n_1)$ of the so-called Holling II (or Monod, or Michaelis–Menten) type. This predator-prey model predicts a destabilization of the coexistence equilibrium, accompanied by a Hopf bifurcation to a stable limit cycle, for K large. Thus, an enrichment of the habitat results, paradoxically, in a destabilization of the predator-prey interaction and, for this reason, this phenomenon is called the “paradox of enrichment.”

The Lotka–Volterra competition model (5) describes two logistically growing populations that adversely affect each other’s growth rate through an interference competitive interaction measured by the quadratic mass-action terms. This model predicts a limited number of competitive outcomes. If the interspecific competition is weak compared with the intraspecific competition ($c_1 c_2 < r_1 r_2 / (K_1 K_2)$), then the species coexist in an asymptotically stable equilibrium state. If interspecific competition is too strong ($c_1 c_2 > r_1 r_2 / (K_1 K_2)$), then one species becomes extinct and the other survives (in an asymptotically stable equilibrium state). The Lotka–Volterra competition model gave rise to the

many fundamental ecological notions, including competitive exclusion, ecological niche (there can be no more species than there are limiting resources), and limiting similarity of competitors. Although not universal for theoretical competition models, these concepts are well supported by a large number of other competition models. For example, the exploitative competition model (the chemostat model)

$$\begin{aligned}\frac{dn_1}{dt} &= -dn_1 + \frac{1}{\alpha_1} c_1 \frac{R}{a_1 + R} n_1, \\ \frac{dn_2}{dt} &= -dn_2 + \frac{1}{\alpha_2} c_2 \frac{R}{a_2 + R} n_2, \\ \frac{dR}{dt} &= d(R_0 - R) - c_1 \frac{R}{a_1 + R} n_1 - c_2 \frac{R}{a_2 + R} n_2\end{aligned}$$

describes the competition of two species for a (prey) resource R . This model also predicts the survival of only one species (Smith & Waltman, 1995).

Large-dimensional ecosystems can be modeled by coupling together any number of single species such as those described above (May, 2001). Such multispecies models can include temporal, spatial, and/or demographic inhomogeneities. For example, the dispersal and diffusion of many interacting species can be modeled by systems of reaction-diffusion equations, such as Fisher's equation, coupled together so as to describe predator-prey or competition interactions. Similarly, coupled systems of McKendrick equations or Leslie matrix models describe interactions among structured species.

POWER BALANCE

As the dynamics of any real system includes dissipation, steady dynamic regimes are observed if energy loss is permanently compensated by energy input from some external or intrinsic source, which is a condition of power balance (PB). In the flame of a candle, for example, power input is supplied by the burning wax and dissipation by the emission of heat and light. Starting from the seminal theoretical work by Yakov Zeldovich & David Frank-Kamenetsky (1938), the modern combustion theory has developed a detailed mathematical analysis of the flame propagation in various combustible media, based on the PB concept (Williams, 1964).

The PB analysis in its general form underlies a variety of dynamical phenomena in physics, chemistry, biophysics, and engineering. A simple model is the van der Pol oscillator, which is described by the equation

$$\ddot{\xi} + \omega^2 \xi = \alpha \dot{\xi} - \beta \xi^2 \dot{\xi}. \quad (1)$$

Here, $\xi(t)$ is a dynamical variable, ω is the eigenfrequency of linear oscillations in the system, and the small positive coefficients α and β account for the linear intrinsic gain and nonlinear loss, respectively. As the energy (E) of this system is $(\dot{\xi}^2 + \omega^2 \xi^2)/2$, Equation (1) implies

$$dE/dt = (\alpha - \beta \xi^2) \dot{\xi}^2. \quad (2)$$

Assuming that $\xi = A \cos \omega t$, averaging Equation (2) over a cycle, and assuming that $(dE/dt) = 0$, one finds that PB is established at the amplitude $A = 2\sqrt{\alpha/\beta}$.

Another generic case is the balance between intrinsic loss and energy supplied from an external source. An example is furnished by an equation for an ac-driven damped pendulum with sinusoidal nonlinearity,

$$\ddot{\xi} + \sin \xi = -\alpha \dot{\xi} + \gamma \cos(\omega_0 t), \quad (3)$$

where $\alpha > 0$ is a friction coefficient and γ and ω_0 are the amplitude and frequency of the drive. (An important realization of this equation is a Josephson junction. In this case, ξ is the phase difference of the superconducting wave function across the junction, α accounts for ohmic loss, and the ac drive is induced by bias current applied to the junction (Barone & Paternó, 1982).) The corresponding PB equation takes the form (cf. Equation (2))

$$dE/dt = -\alpha \dot{\xi}^2 + \gamma \dot{\xi} \sin(\omega_0 t). \quad (4)$$

In the lowest-order approximation, $\alpha = \gamma = 0$, two different types of exact solution are known: oscillating and rotating ones with zero and finite average velocity ($\dot{\xi}$), respectively. Substitution of the rotating solution into Equation (4) (where α and γ are treated as small parameters) and averaging over the period shows that PB is established for the solution whose frequency is

locked to the driving frequency ω_0 , so that $\omega = \omega_0/n$, $n = 1, 2, \dots$. In other words, the PB condition selects the solution's frequency. Further, it follows from Equation (4) that the PB condition cannot be met unless the drive's strength exceeds a finite threshold value, γ_{thr} .

At $\gamma > \gamma_{\text{thr}}$, the PB between the ac drive and loss selects a constant value of the phase shift ϕ_0 between the ac drive and the phase of the oscillating part of the solution. Indeed, averaging Equation (4) and demanding $\langle dE/dt \rangle = 0$ yield a general result, $\cos \phi_0 = \gamma_{\text{thr}}/\gamma$; that is, there are two power-balanced solutions, $\phi_0 = \pm \cos^{-1}(\gamma_{\text{thr}}/\gamma)$. Further analysis demonstrates that one solution is stable and the other one is unstable.

A similar mechanism underlies propagation of a magnetic-flux quantum (fluxon, or topological soliton) in a long weakly damped ac-driven Josephson junction with periodic spatial modulation, which is described by the following sine-Gordon (SG) equation:

$$\begin{aligned} \xi_{tt} - \xi_{xx} + [1 + \varepsilon \sin(2\pi x/\lambda)] \sin \xi \\ = -\alpha \xi_t + \gamma \cos(\omega_0 t). \end{aligned} \quad (5)$$

Here x is the coordinate along the Josephson junction, the subscripts stand for partial derivatives, and ε and λ are the amplitude and period of the spatial modulation. In this case, the average velocity (v) of the ac-driven fluxon is determined by the condition of locking the frequency of the periodic passage of the spatially periodic relief by the fluxon to the ac-drive's frequency, which yields a spectrum of PB velocities: $\langle v \rangle = \lambda \omega_0 / (2\pi n)$, $n = \pm 1, \pm 2, \dots$. Note that the sign of the velocity is determined by an initial push setting the fluxon in motion.

The latter phenomenon was observed in a direct experiment, in the form of an *inverse Josephson effect*, that is, dc voltage induced by ac bias current (Ustinov & Malomed, 2001). The periodic spatial modulation is necessary for the effect, as it opens a way to establish the PB between the ac drive and dissipation. Nevertheless, in an annular (ring-shaped) Josephson junction of a long but finite length, the same effect is possible without any spatial modulation, due to the interaction of the fluxon with its own tail (Goldobin et al., 2002). In that case, the average velocity is not "quantized," as above, but may take any value. A noteworthy feature, specific to the ring system, is the dependence of the threshold value γ_{thr} on the ring's length L (see Figure 1). (If the driving signal is slightly nonmonochromatic, progressive motion is still possible over a long time, but it is eventually destroyed by decoherence accumulating due to small fluctuations of the driving frequency (Filatrella et al., 2002.) PB for breathers in long lossy Josephson junctions is also possible (Lomdahl & Samuelsen, 1986).

Another class of PB problems can be formulated in terms of the complex Ginzburg–Landau equation, which may be regarded as a perturbed version of the

Figure 1. The minimum (threshold) value of the ac-drive's strength γ , in the case $\varepsilon = 0$, $\omega = 1.12$, and $\alpha = 0.1$ [see Equation (5)], which is necessary to support progressive motion (in either direction) of a fluxon in a long Josephson ring, vs. the length (L) of the ring. In regions without data, the ac-driven motion of the fluxon is impossible; in particular, the effect vanishes if L exceeds $L_{\text{max}} \approx 21$.

nonlinear Schrödinger (NLS) equation:

$$\begin{aligned} iu_t + \frac{1}{2}u_{xx} + |u|^2u = -i\alpha_0u + i\alpha_1u_{xx} \\ + i\alpha_2|u|^2u - i\alpha_3|u|^4u, \end{aligned} \quad (6)$$

where all the coefficients $\alpha_{0,1,2,3}$ are assumed to be positive and small. In this model, linear and quintic nonlinear losses are accounted for by α_0 , α_1 , and α_3 , respectively, while α_2 is a cubic-gain coefficient. Equation (6) describes transmission of soliton signals in nonlinear fiber-optic telecommunication links with loss, gain, and filtering (the last being represented by the term α_2 term) (Iannone et al., 1998) and subcritical pulses observed in binary-fluid thermal convection in narrow channels (Kolodner, 1991).

The energy of the optical field in the fiber is $E = \int_{-\infty}^{+\infty} |u(x)|^2 dx$, and the loss and gain terms on the right-hand side of Equation (6) give rise to the corresponding PB equation,

$$\begin{aligned} dE/dt = 2 \left[-\alpha_0 E + \int_{-\infty}^{+\infty} (-\alpha_1 |u_x|^2 \right. \\ \left. - \alpha_3 |u|^6 + \alpha_2 |u|^4) dx \right]. \end{aligned} \quad (7)$$

Approximating solutions by the NLS soliton, $u = \eta \operatorname{sech}(\eta x) \exp(i\phi)$, where η is an amplitude, substituting this in Equation (7) and equating dE/dt to zero lead to a PB condition in the form

$$\eta [8\alpha_3 \eta^4 - 5(2\alpha_2 - \alpha_1) \eta^2 + 15\alpha_0] = 0. \quad (8)$$

The trivial solution, $\eta = 0$, is stable. The remaining factor in Equation (8) yields two nontrivial solutions if threshold conditions are satisfied: $\alpha_2 > \alpha_1/2$ and $5(2\alpha_2 - \alpha_1)^2 > 96\alpha_0\alpha_3$. The solution with a larger value of η gives a stable SP, and the one with smaller η is unstable.

Another manifestation of PB occurs in reaction-diffusion systems, such as the FitzHugh–Nagumo model (Cross & Hohenberg, 1993). Besides chemical systems—the Belousov–Zhabotinsky (BZ) reaction, heterogeneous catalysis, and so on—models belonging to this class find numerous other applications, including neural networks, cardiac tissue in biophysics, electron-hole plasmas in semiconductors, and gas-discharge plasmas. In this case, the PB takes place between energy release due to the chemical reaction, which is described by local terms of the model, and loss due to diffusion. As a result, various patterns may be supported as stable dynamical equilibria, including standing or traveling waves, fronts (shock waves) and periodic wave trains in one dimension, spiral vortices and localized spots in the two-dimensional case, and vortex rings in three dimensions, among others. An interesting experimental finding is the observation of two drastically different regimes of propagation of a BZ chemical wave in aqueous solution, which resemble deflagration and detonation waves in gas dynamics: a slow wave, which is driven by diffusion of chemical reactants, and a fast “big wave” (Inomoto et al., 1997), which is coupled to surface deformation and flow in the solution. The two modes of the chemical-wave propagation realize the PB in different forms, the choice between them being determined by the initial perturbation.

PROTEIN DYNAMICS

Proteins carry out structural, catalytic, and molecular recognition roles that require a wide variety of motions over a broad range of timescales, from 10^{-15} to 10^3 s, as sketched in Figure 1. Motions can be as mundane as coupled vibrations or as sophisticated as gene transcription by an RNA polymerase protein. The broad range of timescales is a principal difficulty in understanding protein dynamics. We will focus here on atomic motions and conformational changes of single proteins.

Although there are a wide variety of proteins displaying many remarkable dynamical phenomena, photoactive proteins play a special role in experimental studies of protein dynamics. This is because experiments can be initiated with a femtosecond laser pulse at any temperature from absolute zero to the unfolding temperature of the protein, allowing the wide variety of motions to be observed. Proteins which have been extensively studied this way are myoglobin (Austin et al., 1975), the photosynthetic reaction center, rhodopsin, photoactive yellow protein, and cytochrome oxidase.

An essential result of such studies is that there are three fundamentally different processes involved in modeling atomic motions of proteins. This distinction can be seen in the temperature-dependent rates of various processes observed in myoglobin, sketched in Figure 2 and described in Fenimore et al. (2002). These processes are labeled as fast fluctuations, bond formation, and conformational motions.

Fast fluctuations occur on the 100 picosecond timescale over the temperature range from 200 to 300 K, but their amplitude (or number) diminishes by a factor of ten over this range. Because these motions

Figure 1. Types of protein motions which occur on timescales from femtoseconds to hours.

occur in the absence of bulk solvent motions, they must involve relatively local rearrangements between the various possible meta-stable configurations possible in a protein. The network properties of water at the surface of the protein and the voids created by thermal expansion play an important role in these types of motion; the motions disappear when a protein sample contains less than about 30% water.

It is possible to capture the essence of these motions with a relatively simple potential energy function and Newton's law of motion, $F = ma$, $V =$ bond stretch + bond angle + dihedral twist + atom-centered point charge electrostatics + Lennard-Jones.

The bond stretch and bond angle terms are simple harmonic potentials which allow the protein to vibrate. The dihedral twist term is a cosine function which allows transitions between rotamer states of single and double bonds. Dihedral twist parameters of the backbone will also influence the relative free energy of alpha helixes and beta sheets, two of the common secondary structure motifs described in the (*See Protein structure*). Much of the subtlety in this potential energy function lies in the electrostatics and Lennard-Jones terms. Both are pairwise additive interactions between atoms that are not bonded to each other or through another atom. The electrostatic interaction strength falls off as $1/d$, while the Lennard-Jones term is of the form $A/d^{12} - B/d^6$, where d is the distance between atoms.

When the solvent is treated explicitly, parameters can be developed which reproduce important dynamic and thermodynamic properties that contribute to protein function. These include solvent properties, such as dielectric response time and amplitude, self-diffusion coefficients, and heat of vaporization. For amino acids and other small molecules, heats of solvation and heats of transfer from octanol to water are accurately reproduced. Heats of solvation and some aspects of the hydration shells of ions are also correctly modeled.

When this potential energy function is applied to protein folding and dynamics, it produces a prediction for the ensemble of protein conformations, as well as rates of water penetration, motions of loops, folding temperature, and the ensemble of unfolded states.

Figure 2. Arrhenius plot, showing the temperature-dependent rates of three types of experimentally measured protein motions, compared with the rate of solvent motions. (Taken from Fenimore et al., 2002, and references therein.)

In practice, it is difficult or impossible to obtain the necessary sampling to unambiguously quantify these properties. The reason is that a solvated protein simulation involves about 30,000 atoms; thus the integration time for the dynamics is limited to about 2 fs, while many of the motions of interest occur on the nanosecond to microsecond timescales (see Figure 2). Much effort in this field over the past two decades has centered on methods to improve the sampling through efficient implementation, parallelization, and statistical physics.

Covalent bond formation is the primary function of enzymes and involves many of the complexities of fast fluctuations combined with the need for a quantum-mechanical description of electronic polarizability, bond distortion, and bond formation. Such descriptions are available through all-electron quantum chemistry techniques, such as density functional theory, but calculations require approximately 1 cpu/day to evaluate energies and forces for 200 atoms. Calculations can be efficiently parallelized, and when more than 200 protein atoms are included, computation time scales linearly with system size. It is also possible to treat the bond-formation region quantum mechanically and the rest of the protein and solvent classically in a single calculation.

The difficulties involved in computing reaction rates include proper treatment of the vibrational dynamics of bond formation, sampling over hydration states, and sampling over the ensemble of protein conformations. One useful simplification is that many enzymes exclude water from their active site, considerably reducing the disorder.

Conformational motions of proteins can involve simple shifts of helixes, repacking of amino acid side chains, or more extensive changes between active

and inactive conformations. The molecular dynamics model described above makes a prediction for conformational changes of proteins, but it is only recently that computer power has reached the long times necessary to test these predictions (Karplus & McCammon, 2002; Mayor et al., 2003). It is likely that some tuning of parameters will be necessary to predict protein properties with the same reliability with which these models currently predict small molecule properties.

Because the solvent provides a cage which prevents the protein from moving freely, the fraction of possible configurations explored increases by several orders of magnitude when the solvent is considered implicitly (Takada, 1999). While it is doubtful that a single parameter set can be developed to treat all proteins with an implicit solvent, it is clear from models of protein folding that much can be learned from implicit solvent models which are explicitly, but weakly, biased toward a known folded conformation.

PROTEIN STRUCTURE

A protein's structure, flexibility, and activity depend on the primary sequence of amino acids encoded by DNA, the presence of small-molecule ligands, the presence of protein or nucleic acid binding partners, and its history of covalent modification by other enzymes. Figure 1 (in color plate section) shows the catalytic site of one protein, RNA polymerase. This protein is responsible for transcribing an organism's DNA into messenger RNA, initiating the process of protein production, an essential

and highly regulated cellular process. The complex geometry of interactions which stabilize the DNA, RNA, and nucleotide being added to the RNA are highly conserved among polymerases from all organisms, from microbes to humans. It is typical of enzymes that they are precisely (within about 0.1 Å) constructed near the catalytic site in order to exclude water and polarize and orient the reactants, yet still maintain the flexibility to allow reactants to enter and exit the active site.

One reason proteins can adopt highly rigid active sites, yet still undergo the large motions necessary for substrate binding, is that the peptide backbone is stabilized by multiple interactions in particular structural motifs, such as helices, sheets, and particular types of hairpin turns. Thus, not only are the residues directly responsible for catalysis highly conserved among organisms, but also the arrangement of helices, sheets, and tightly packed hydrophobic residues which determine the large-scale dynamics of the protein. This is illustrated in page 7 of the color plate section, which shows the entire catalytic domain of RNA polymerase, color-coded according to the polarity and charge of the amino acids. It is useful, looking at this figure, to reflect on the numerous cooperative interactions among the 1034 amino acids of this protein which cause it to fold up in this shape, rather than the shape of any of the other 30,000 proteins, or a glob of tangled polymer. These interactions are predominantly hydrophobicity, shape, hydrogen bond formation, and charge complementarity.

Protein function entails not only catalysis, but also the ability to be regulated by other proteins. This is done either by covalent modification, such as phosphorylation (covalent attachment of PO_3^{2-}) or acetylation (covalent attachment of C_2O), or by complex formation with other proteins. In either case, all the residues at the surface and the geometry of rigid motifs communicating the surface interactions to the active site become important determinants of protein structure. This is illustrated in the color plate section, showing the complex of twelve proteins, DNA, and RNA that is required for RNA polymerase to transcribe DNA to messenger RNA, as an early step in protein synthesis.

We have used the polymerase protein to illustrate several aspects of protein structure. There are between 10,000 and 100,000 types of protein structures used in various organisms, and a significant fraction of them have had their structure experimentally determined by diffraction of X-rays from a protein crystal. These structures are collected in a publicly accessible protein data bank, and several free software programs exist to aid in visualizing various aspects of protein structures.

The single, most important determinant of a protein's structure is the primary sequence of amino acids, encoded by an organism's DNA. Advances in microbiology have allowed automated sequencing of

complete genomes of numerous organisms. While tens of thousands of protein structures are known, several million protein sequences are known, from all types of living creatures, from mammals to plants, microbes, and viruses. Proteins can be identified from their sequence of amino acids by searching for patterns of amino acids with BLAST (basic local alignment search tool), or tailoring a search algorithm based on numerous examples of a particular protein with a so-called hidden Markov model. Sequence analysis has been used to annotate both complete and partial genomes, and the results are available in several public databases.

The great excess of sequence data over structural data, combined with the insight into protein function and interactions provided by knowledge of the protein structure, provokes the question of whether it is possible to predict a protein structure from its primary sequence of amino acids. The essential reason this problem is difficult is that amino acids have an average of four dihedral angles which are equally stable in any of two or three positions (0° , $+120^\circ$ and -120°), creating $3^4 \times 150$ possible structures for each protein. The second reason is that when proteins were optimized by evolution, they exploited subtleties of interactions which are not necessarily captured by simple potential energy functions. Thus, while it has long been clear what forces stabilize folded proteins (hydrophobic interactions, hydrogen bonding, and Coulomb interactions), it has only recently been possible to relate the folding of a sequence of 20 amino acids to interaction potentials derived from small-molecule thermodynamic properties.

When it is possible, the most reliable method to predict a protein's structure is to find a protein of known structure which has greater than about 30% sequence identity. The particular conformations of most amino acids can then be inferred from the known protein structure, and resulting problems can usually be corrected by a Monte Carlo search algorithm or by hand. This process is known as homology modeling. Systematic efforts have produced enough experimentally determined structures to cover most of the observed sequences.

If a suitable template protein is not available, the protein structure must be constructed from observed structural motifs. Three of the most useful rules are: (1) hydrophobic residues tend to occupy the interior of the protein; (2) beta sheets, alpha helices, and other types of turns have characteristic amino acid content; and (3) triplets of amino acids tend to make particular configurations. Progress in this so-called ab initio folding can be evaluated by observing the result of the CASP competition, where a dozen experimentally determined structures of novel proteins are held back, while competing research groups are given several months to enter predictions of their structures.

PUMP-PROBE MEASUREMENTS

Figure 1 shows a prototype pump-probe experiment in which short pump-laser pulse excites the vibrational oscillator (used here as a simple example) from the $\nu = 0$ vibrational state into the $\nu = 1$ vibrational state. A subsequent probe-laser pulse tests the $\nu = 1$ population by probing the $\nu = 1 \rightarrow \nu = 2$ excited state absorption, the $\nu = 1 \rightarrow \nu = 0$ stimulated emission, and/or the $\nu = 0 \rightarrow \nu = 1$ bleach. The time resolution of such an experiment is given by the pulse duration of the laser pulses, while the detector can be slow. With recent progress in laser technology, one can now perform pump-probe experiments in almost any spectral range, starting from far-IR (10 cm^{-1}) to soft X-ray radiation (1 keV) with a time resolution of much less than a picosecond (2000).

Pump-probe spectroscopy is a special form of third-order nonlinear spectroscopy. The theory of linear and nonlinear optical spectroscopy is generally performed in a perturbative expansion, where the electric fields of the light pulses act as weak perturbation onto the molecular Hamiltonian. The linear response, which

Figure 1. (a) A prototype pump-probe setup and (b) a prototype pump-probe experiment of a vibrator.

describes linear absorption spectroscopy, is given by

$$P^{(1)}(t) = \int_0^\infty dt_1 R^{(1)}(t_1) \times E(t - t_1). \quad (1)$$

Expressed in simple words, the electric field E of the probe light interacts once with the sample through the first-order response function $R^{(1)}$, generating a first-order polarization $P^{(1)}$, which subsequently is measured in the detector. The first-order response function $R^{(1)}$ is a material property, which can be tested by this type of spectroscopy. For instance, if the electric field E is chosen to be a monochromatic wave, one can measure the absorption spectrum by tuning its frequency.

Third-order spectroscopy is given by

$$P^{(3)}(t) = \int_0^\infty dt_3 \int_0^\infty dt_2 \int_0^\infty dt_1 R^{(3)}(t_1, t_2, t_3) \times E_1(t - t_3) E_2(t - t_3 - t_2) E_3(t - t_3 - t_2 - t_1). \quad (2)$$

Again expressed in simple words, the electric fields E_1 , E_2 , and E_3 originating from a maximum of three laser pulses (in the example of Figure 1a, both E_2 and E_3 originate from one pulse, i.e., the pump pulse) interact with the sample at three different time points $t - t_3$, $t - t_3 - t_2$, and $t - t_3 - t_2 - t_1$ through the third-order response function $R^{(3)}$, generating a third-order polarization $P^{(3)}$. The third-order response function $R^{(3)}$ contains significantly more information about the molecular system than the linear response function. Both can, in principle, be calculated once all eigenstates, transition dipole moments, and relaxation pathways of a system are known.

There are different types of third-order spectroscopies, the most important of which being pump-probe and photon echo spectroscopy. Both exist in many variations. They all measure the same third-order response function $R^{(3)}$ but differ by the choice of the three field interactions E_1 , E_2 , and E_3 (timing, frequency, beam direction, etc.). The different methods project different aspects of the complicated third-order response function $R^{(3)}$. A comprehensive discussion of the principles of nonlinear optical spectroscopy is given by (Mukamel, 1995). In the context of nonlinear science, the following advantages of third-order spectroscopies should be noted.

- In condensed phase systems, spectroscopic transitions are often significantly broadened. The most common broadening mechanisms are (i) lifetime broadening (T_1 -relaxation), (ii) homogeneous broadening (T_2 -relaxation), and (iii) inhomogeneous broadening. In solution phase systems, the situation becomes even more complicated since the distinction between homogeneous and inhomogeneous broadening becomes a question of the timescale of the fluctuating forces giving rise to dephasing. As a consequence, a continuous transfer between both regimes does, in general, occur. It is a common practice to fit absorption lines to certain line profiles such as a Lorentzian profile (homogeneous and/or lifetime broadening), a Gaussian profile (inhomogeneous broadening), a Voigt profile (a mixture of both), or a Kubo profile (intermediate regime). However, the assignment to different broadening mechanisms is model-dependent and often extremely questionable. Linear absorption spectroscopy principally cannot distinguish between different broadening mechanisms.

The information boost of third-order nonlinear spectroscopy just makes that distinction possible. For example, pump-probe spectroscopy observes T_1 -relaxation directly by populating a spectroscopic state with the pump-pulse and subsequently observing its relaxation back into the ground state with the probe-pulse (see Figure 1b). Photon echo experiments and transient hole burning experiments (a special form of pump-probe experiment with a spectrally narrow pump-pulses) can distinguish between the homogeneous, inhomogeneous, and the intermediate dephasing regime.

- When considering nonlinear vibrational states, such as the Davydov soliton and/or local modes in molecular crystals, a more subtle point is the following: The nonlinear third-order response of a system of linearly coupled harmonic oscillators (i.e., a crystal described in the harmonic approximation) vanishes exactly. This is because the three contributions to the nonlinear response function (bleach, stimulated emission, and excited state absorption, see Figure 1(b)) all occur at the same frequency, and the transition dipoles are such that they cancel completely. Only anharmonicity (nonlinearity) of the molecular potential surfaces gives rise to a nonzero pump-probe signal. Hence, nonlinear pump-probe spectroscopy is specifically sensitive to that part of the molecular Hamiltonian which is also responsible for collective nonlinear phenomena. A linear absorption spectrum is, of course, nonzero also in the harmonic limit.

Using these properties, one can test predictions from soliton and self-trapping theories in a much more direct way than linear absorption spectroscopy can do. For example, Davydov has speculated about vibrational solitons in protein secondary structures, with the aim to

explain the capability of proteins to efficiently store small quanta of energy (Davydov, 1979). As a first experimental attempt to verify this prediction, Austin and coworkers (Xie et al., 2000) have investigated the lifetime of the amide-I band (mostly the C=O stretching mode of the protein backbone) of myoglobin, which typically relaxes on an ultrafast 1 ps timescale. Interestingly, they found a somewhat prolonged lifetime (15 ps) in the blue wing of the absorption spectrum. Pump-probe experiments on crystalline acetanilide (ACN), a simple model system used to study nonlinear collective phenomena in protein structures (Scott, 1992), have revealed useful information, including the following (Edler et al., 2002): (i) The NH free exciton self-traps on an ultrafast 400 fs timescale. (ii) The phonons that mediate self-trapping can be identified. (iii) The anharmonicity of the amide-I states is a measure of their degree of delocalization. The free exciton is delocalized at a temperature of 90 K but Anderson (disorder) localizes with increasing temperature. On the other hand, the band that has been assigned to a self-trapped state is localized at all temperatures. (iv) The lifetimes of the initially excited states are short (1–2 ps), yet the ground state recovery is somewhat longer

(20–40 ps). Apparently, energy is stored in the meantime by mechanisms that still need to be explored. None of this information can be obtained from linear absorption spectroscopy.

QUANTUM CHAOS

Classical equations of motion can have arbitrary nonlinearities and thus can show a wide variety of chaotic behavior. The Schrödinger equation for quantum systems, in contrast, is a linear partial differential equation, and the initial value problem cannot show chaotic behavior in the usual sense. However, in the transition regions between classical and quantum descriptions, especially for highly excited systems or short de Broglie wavelengths, chaos in classical dynamics will have its effects on quantum dynamics, the eigenstates, and the eigenenergies. The field of quantum chaos deals with the characteristic properties that emerge in this transitional region. Some features are typical for the time evolution of wave functions and closely related to the classical dynamics of trajectories and phase space densities. Others deal with the properties of eigenenergies and eigenstates. Both aspects can nicely be illustrated for hydrogen atoms in external fields.

A first example for the close relation between classical and quantum dynamics is provided by excitations of hydrogen in microwave fields. Exposed to a microwave field of a frequency of 9.923 GHz, a hydrogen atom starting from a state with main quantum number $n = 66$ needs to absorb about 75 photons in order to ionize. Experiments show little ionization for small intensities of the field and a rapid increase to almost complete ionization for larger fields (Figure 1a). A full quantum calculation is prohibitively complicated

because each photon adds one order of perturbation theory. However, an analysis of the classical dynamics of an electron in a Coulomb field and the external microwave field, with Hamiltonian

$$H = \frac{\mathbf{p}^2}{2m} - \frac{1}{4\pi\epsilon_0 r} + Ff(t)\cos\omega t, \quad (1)$$

Figure 1. Microwave ionization of hydrogen atoms. The combinations $n_0\omega^3$ for the frequency and n_0^4F for the field strength are suggested by classical scaling. (Upper) Survival probability and ionization probability for different frequencies ω and different initial states n_0 that give the same scaled frequency as a function of field strengths. (Lower) Scaled threshold amplitude for the 10% and the 90% levels vs. scaled frequency. The comparison with classical simulations (dotted line) is very good and attests to the reliability of classical modelling of this process. For scaled frequencies $n_0^3\omega$ larger than 1, quantum effects become more important. (From Koch & van Leeuwen, 1995, with permission from Elsevier.)

where $f(t)$ describes the envelope of the field, reproduces the observed threshold amplitudes including many of the structures evident in Figure 1b very accurately.

The classical explanation for the fairly sharp onset is that for low field intensities, not all tori are destroyed, and the chaotic regions are separated by tori that block the transitions between them. For higher field intensities, the tori break up, the chaotic regions grow together, and electron trajectories can explore large regions of phase space, eventually escaping to infinity. This break up of tori is classically a rather dramatic event and can thus explain easily a fairly sharp onset of ionization. Many experiments since have verified the dependence on the initial state and the field intensities. Peculiar structures in the quantum ionization curves were also noted and could be explained as quantum effects due to almost degenerate quasienergy states. For the history of the problem and a careful analysis of the experiments and theories, see the review by Koch & van Leeuwen (1995).

Closely related to the microwave ionization of hydrogen is the dynamics of cold atoms in a standing light field. This problem is an experimental realization of the quantized kicked rotor, a standard model in classical and quantal chaos. Many properties of the quantized kicked rotor are described in Casati & Chirikov (1995); the first experimental realization is described in Moore et al. (1994).

For stationary problems, time can be separated and the eigenfunctions and eigenvalues of the Schrödinger equation can be analyzed. A good example is hydrogen in strong magnetic fields when the quadratic part of the vector potential cannot be neglected: the Hamiltonian then becomes

$$H = -\frac{\hbar^2}{2m}\Delta - \hbar\omega L_z - \frac{1}{4\pi\epsilon_0} \frac{1}{r} + \frac{m\omega^2}{2}(x^2 + y^2) \quad (2)$$

with the magnetic field expressed through its cyclotron frequency $\omega_c = eB/(2m)$. In order for the energy content in the cyclotron motion to be compatible to the spacing between the ground state and the first excited state, the magnetic field has to be of the order of 10^5 T, values reached and exceeded on the surface of neutron stars only. However, if the initial state is an excited state with main quantum numbers of about $n = 40$, already a few Tesla suffice to bring the system way out of the linear Zeemann regime and to scramble the spectra completely (Figure 2). Many properties of the system are described in Friedrich & Wintgen (1989), and in the contribution by Delande to Giannoni et al. (1991).

In such strong fields, there are not enough quantum numbers anymore to allow one to label the eigenstates uniquely. In a similar situation, nuclear physicists introduced statistical measures for the distribution of eigenvalues (See **Random matrix theory**).

Figure 2. Energy levels for hydrogen in a magnetic field, for field strengths up to 7 T and initial quantum numbers between 38 and 45. The linear splitting within the Zeemann regime is limited to a region with very small fields. Most of the apparent crossings between eigenvalues are in fact avoided. (From Friedrich & Wintgen, 1989, with permission from Elsevier.)

Many investigations have shown that the statistics of eigenvalues for hydrogen in sufficiently strong magnetic fields, such as the level spacing distribution or two point correlation functions, are in very good agreement with random matrix theory (Friedrich & Wintgen, 1989). The same applies to many other classically chaotic systems, including vibrations of molecules, particles trapped in billiards, and model Hamiltonians with cubic and higher-order potentials, see the contribution by Bohigas to Giannoni et al. (1991) and the books by Brack & Bhaduri (1997), Haake (2001), and Stöckmann (1999).

While the distribution of eigenvalues shows statistical features, there are also deterministic ones: the Gutzwiller trace formula relates in the semiclassical limit eigenvalues E_i of the quantum system to classical periodic orbits and their properties (Gutzwiller, 1990; Chaos Focus Issue, 1992; Friedrich & Eckhardt, 1997),

$$\rho(E) = \sum_i \delta(E - E_i) \sim \text{Re} \sum_p A_p e^{iS_p(E)/\hbar}, \quad (3)$$

$S_p = \oint p \, dq$ is the classical action. The amplitude A_p carries information about caustics (through their phase shifts) and the instability of the classical orbits: the more unstable the smaller the weight. Because the density of states follows from a quantum amplitude (rather than a probability), the quantum amplitude is in magnitude the square root of the classical probability amplitude (See **Periodic orbit theory**). Expanding linearly around some reference energy E_r , the action becomes $S(E) \approx S(E_r) + T(E_r)(E - E_r)$, and a Fourier transform in E will result in peaks at the periods of periodic orbits in the system. This was noted in experiments by Karl Heinz Welge and his group and in numerical calculations by Friedrich & Wintgen (1989) (see also the comparison in Figure 3). Thus, on energy scales larger than a mean spacing

Figure 3. (Upper) The periodic orbits with periods S less than 3 and their semiclassical amplitudes and (Lower) a Fourier transform of a cross section of the quantum spectra in Figure 2.

and compatible with classical dynamics, the density of states is modulated by periodic orbits. Such periodic orbit spectroscopy can be used to extract the orbits and, thus, system specific properties.

In the presence of large-scale classical chaos and the accessibility of large parts of phase space by a single trajectory, one might expect that the wave functions are fairly uniformly spread out over the classically ergodic region. For billiards, this is the content of Shnirelman's theorem. However, as first discussed by Heller (1984) (see also Heller's contributions to Giannoni et al., 1991), periodic orbits leave their imprint on wave functions. One can find an enhanced intensity near a periodic orbit (a "scar") that can be detected in enhanced cross sections for certain processes.

The possibilities of quantum chaos are not limited to the realm of quantum phenomena proper: all that is needed is a wave theory, ideally with a classical dynamics for the propagation of wave fronts in the short wavelength limit. Examples outside the quantum world include resonances in microwave cavities, vibrations of solids, and acoustic waves in concert halls. In all cases level repulsion and other features can be found.

Many of the general properties of chaotic wave systems are discussed in the review Eckhardt (1988); in the textbooks by Brack & Bhaduri (1997), Gaspard (1998), Gutzwiller (1990), Haake (2001), and Stöckmann (1999); and in the contributions to Casati & Chirikov (1995), Giannoni et al. (1991), Chaos Focus Issue (1992), and Friedrich & Eckhardt (1997).

QUANTUM FIELD THEORY

As our most fundamental description of physical phenomena, quantum field theory (QFT) is the natural culmination of classical mechanics, classical field theory, and quantum mechanics. To understand what QFT is and what makes it so special, it is worthwhile to briefly look at each of these structures in turn.

Classical mechanics describes the motion of objects in space and time in terms of well-defined positions and momenta that, taken together, form the phase space of the system. The location of an object in phase space can, in principle, be determined at any time, and once known suffices to predict its location at all future times given a complete enough knowledge of the forces at work. There are two main formulations of classical mechanics: the Hamiltonian formulation, which concentrates on how to find quantities at later times in terms of their known values at earlier times, and the Lagrangian one, which derives the same information from variational principles. These principles state that an object's trajectory in phase space extremizes a certain quantity called the action, which is the integral over the whole phase space history of a

functional called a Lagrangian. The dimension of the phase space is usually finite, but can be enlarged beyond the usual $3+3$ dimensions for the location and velocity of a point particle to allow for rotations of a rigid body or changes of shape of a deformable body. Relativity can be accommodated, but the ideas of quantum mechanics do not appear.

The move to an infinite number of phase space dimensions takes one from classical mechanics to classical field theory. Fluid mechanics, for example, allows for an infinite variety of shapes that a fluid can take making the phase space infinite. Sums that arose in classical mechanics are now integrals, and the general problems of analysis become much more challenging. Nevertheless, many problems are tractable, and theories based on classical fields with an infinite number of degrees of freedom have had great success. Notable among these is Maxwell's electrodynamics, which describes the electromagnetic field in terms of electric and magnetic fields that can vary in space and time and are present at all points of space and time. The phase space of classical electromagnetism is then infinite dimensional, and this accounts for much of the richness of the physics that it can describe.

Another shift away from classical mechanics is to maintain a finite number of degrees of freedom but to allow that points in phase space cannot be arbitrarily well known. The Heisenberg uncertainty principle placed constraints on the accuracy with which position and momentum could be known simultaneously, and the points of the phase space acquired a certain fuzziness. For example, in place of a point with well-defined position x and momentum p_x in the x -direction, one had something like a fuzzy disk of area roughly equal to the square of the Planck length, and shape determined by whether one tried to accurately determine x or p_x —one could only know one with a consequent sacrifice of information about the other. A system cannot now be thought of as a well-defined classical point moving around in phase space. Rather, information about the system is encoded in a function on the phase space called the wave function Ψ , and the theory allows all that can be known about the system to be recovered by applying various linear operators to Ψ .

The step to QFT involves allowing an infinite number of degrees of freedom in quantum mechanics. Thus, one might say that QFT is to quantum mechanics what classical field theory is to classical mechanics. The shift is profound and carries a number of important implications.

The first is that QFT takes as its phase space classical fields upon which an uncertainty paralleling that in quantum mechanics has been imposed. For example, the role of x could be taken by a classical field ϕ , and the role of momentum p_x by the rate of change of something (the Lagrangian) with respect to the time derivative of ϕ . This quantity is called the momentum

conjugate to ϕ , and it is impossible to know both it and ϕ with arbitrary precision.

Time and space are now just dummy labels (parameters) in the theory and are integrated over, their main use being to enforce the notion of locality in a Lagrangian. This point is often misunderstood as people look for the "locations" of field quanta in physical space. In QFT, one looks at ϕ as a dynamical quantity as opposed to x . An excellent discussion of this point can be found in Schwinger (1970).

It turns out, perhaps somewhat tautologically, that one can often expand fields in Fourier series and identify each of the modes as a "particle" with momentum given by the mode numbers. It is a remarkable fact that experiments to detect fields in nature, when performed with sufficient resolution, always find them occurring in (or at least interacting as) discrete chunks or quanta. In this sense, QFT is a theory of particles, and the degree to which these quanta can be identified as isolated, discrete objects determines how well they can be thought of as particles.

As a field changes in time so too do the various Fourier modes and this is interpreted as saying that particles appear and disappear; in other words, particles can be created and destroyed in QFT. This is something foreign to both quantum and classical mechanics and was needed with the advent of high-energy physics experiments in which particles are routinely created and destroyed.

Two of many excellent texts describing how QFT is used in the calculation of physical processes are those by Peskin & Schroeder (1995) and by Weinberg (1995). The text by Itzykson and Zuber (1980) is also very good. A more philosophically inclined and less calculationally oriented reader will find much to think about in the book by Teller (1995). It is easy to suppose that QFT is intrinsically, or somehow must be, relativistic. In fact, the concepts can be very successfully applied to problems in condensed matter physics in nonrelativistic situations, and the interested reader will find the delightful introductory book by Mattuck (1992) and the more advanced book by Abrikosov et al. (1975) excellent places to start.

Several caveats are in order. First of all, in the relativistic case (the real world), these quanta do not generally admit a localization in the sense of having well-defined classical-like positions. That is, they do not behave like billiard balls. Second, if interactions between them are very strong they may not act as intuition might suggest. For example, while electrons and photons are in many ways like what one might expect particles to be, protons and neutrons seem to be comprised of particles called quarks, which cannot be removed. One says that the interactions between quarks are so strong that they are "confined." Phonons are quantized vibrations in crystals that can be detected in neutron scattering experiments and act in many ways

Figure 1. A Feynman diagram representing a first approximation to the scattering of one electron from another (the two straight lines) via the exchange of a photon (the wiggly line). Each diagram like this corresponds to a physically clear picture as well as to a well-defined mathematical expression contributing to the quantum mechanical amplitude for the process to take place. Only the topology of the diagram is important. Bending the lines around represents processes involving electrons and their antiparticles as different aspects of the same basic phenomenon, and connects scattering in space with scattering forward and backward in time, while not violating causality.

like particles, but they are only there insofar as there is a crystal lattice to vibrate. Any attempt to isolate a phonon by pulverizing a crystal and looking for one among the fragments is doomed to failure.

When it makes sense to think of weakly coupled particles, there is a well developed calculational framework called “perturbative quantum field theory” (pQFT), which allows one to make systematic estimates of physical quantities, often using sketches called Feynman diagrams. Figure 1 shows a Feynman diagram contributing to the scattering of one electron by another (the straight lines) via the exchange of a photon (the wiggly line).

The mathematical procedures involved are fraught with difficulties, and the series that arise are often divergent on physical grounds. In addition, the individual terms also tend to be infinite, and several procedures have been developed for handling such problems. The general approach is to first make ill-defined formal expressions finite by changing them (“regularizing” them) in a way controlled by some parameter, then comparing such regularized expressions only to one another and linking only such comparisons to observations (“renormalization”). Despite the feelings of many of the founders that there might be something deeply wrong with these procedures, it turns out that many quantities calculated in this way have given answers accurate to parts per million or better.

For strongly interacting theories the state of the art is much less well-developed. Powerful computers can be used to treat theories that are based on restricting fields to live on a grid or lattice that is meant to approximate space–time, but with a finite number of points. Analytic techniques also offer some hope, but the problems are formidable.

One of the most dramatic consequences of QFT is that the vacuum becomes a very complex object. Recalling the notion of the uncertainty principle applied to fields, one cannot set both a field and its conjugate momentum equal to zero. This, in fact is the case for each possible mode of a field and leads to an infinite energy in the vacuum due to these fluctuating, uncertain fields. As mentioned earlier, infinities like this are basically swept under the rug by insisting that only comparisons are meaningful, but in this case there are remarkable physical consequences.

For example, there are more modes that can exist for the electromagnetic field between two parallel metal plates that are far apart than for ones that are closer together. The infinite energies between the plates in these two cases can be compared and the result is finite—there is less energy between two plates that are close together than two that are far apart. This implies that two parallel metal plates, in order to reduce the energy between them (in empty space), will pull together. This is called the “Casimir effect” and has actually been observed in the laboratory, making it clear that QFT and its strange vacuum are more than theoretical fantasies.

Although it is often not made clear, one final aspect of QFT that differs from quantum mechanics is that QFT admits an infinite number of distinct vacua, all of zero energy. None of these vacua can be reached from another by a unitary transformation, making them physically distinct. This richness of “empty” space is a critical part of what makes QFT able to describe so much. To do justice to this point would require more space than is available, but the interested reader would do well to start with the book by Umezawa (1993). One consequence of this existence of unitarily inequivalent vacua is the amazing fact that the vacuum of one observer can be devoid of particles, while that of another may actually have particles present.

QUANTUM INVERSE SCATTERING METHOD

The extension of the inverse scattering method to quantum theory, called the quantum inverse scattering method (QISM), was introduced at the end of the 1970s by the Leningrad (now St Petersburg) group and has been developed extensively since the 1980s. The QISM is significant in many respects. First, similar to the classical inverse scattering method, it provides a powerful method to solve the problem of quantum integrable systems. Second, it has a wide applicability to quantum particle systems, quantum field theoretic models, and quantum spin systems. Importantly, the QISM provides a unified view on exactly solvable models in physics. That is, it places completely integrable models in many-body theory and field theory and solvable models in statistical mechanics in a unified framework. Third, it has been the source of new mathematical objects and concepts such as Yangian algebra, quantum groups, q -deformation, and a revived knot theory. In these mathematical developments, the Yang–Baxter relation plays a central role.

As the simplest example, we begin with the quantum nonlinear Schrödinger (QNLS) model,

$$i\phi_t + \phi_{xx} - 2\kappa\phi^\dagger\phi\phi = 0. \quad (1)$$

Here, $\phi(x, t)$ is the boson field operator, satisfying the equal-time commutation relation, $[\phi(x, t), \phi^\dagger(y, t)] = \delta(x - y)$. The Hamiltonian of the system is

$$H = \int dx (\phi_x^\dagger \phi_x + \kappa \phi^\dagger \phi^\dagger \phi \phi). \quad (2)$$

The QNLS model (1) is considered to be the second-quantized theory of boson particles interacting via the pair-wise, delta-function potential. Motivated by the Zakharov–Shabat eigenvalue problem in the classical theory, we associate a linear auxiliary problem to (1),

$$\begin{aligned} \psi_{1x} + \frac{i}{2}\lambda\psi_1 &= i\alpha\phi^\dagger\psi_2, \\ \psi_{2x} + \frac{i}{2}\lambda\psi_2 &= i\varepsilon\alpha\psi_1\phi, \end{aligned} \quad (3)$$

where $\alpha = |\kappa|^{1/2}$ and ε denotes the sign of κ . We further assume the boundary condition $\phi(x) \rightarrow 0$ as $|x| \rightarrow \infty$, which is interpreted as the weak relation (a relation for the matrix elements). The Jost function operator $\Psi(x, \lambda)$ is defined by

$$\Psi(x, \lambda) = \begin{bmatrix} 1 \\ 0 \end{bmatrix} \exp\left(-\frac{i}{2}\lambda x\right), \quad x \rightarrow \infty,$$

$$= \begin{bmatrix} A(\lambda) \exp\left(-\frac{i}{2}\lambda x\right) \\ B(\lambda) \exp\left(\frac{i}{2}\lambda x\right) \end{bmatrix}, \quad x \rightarrow -\infty. \quad (4)$$

The coefficients $A(\lambda)$ and $B(\lambda)$, corresponding to the transmission coefficient $a(\lambda)$ and the reflection coefficient $b(\lambda)$ in the classical theory, are called scattering data operators. The auxiliary problem (3) with (4) is solved perturbatively to express $A(\lambda)$ and $B(\lambda)$ in terms of the operators ϕ and $\phi^\dagger$ (direct problem). As a result, we obtain

$$[H, A(\lambda)] = 0, \quad [H, B(\lambda)] = -\lambda^2 B(\lambda). \quad (5)$$

The former relation proves that the QNLS model has an infinite number of conserved operators. The latter indicates that the state

$$|k_1, k_2, \dots, k_n\rangle = B^\dagger(k_1)B^\dagger(k_2)\dots B^\dagger(k_n)|0\rangle, \quad (6)$$

where $|0\rangle$ is the vacuum state $\phi(x)|0\rangle=0$, is an eigenstate of the Hamiltonian. Similar to the classical theory, the quantum Gel'fand–Levitan equation can be derived (inverse problem).

The state $|k_1, k_2, \dots, k_n\rangle$ in (6) is valid irrespective of the sign of κ and describes the continuous state (Bethe ansatz state). For the attractive case ($\kappa < 0$), there appear bound states. A bound state (n -string state) is made of the complex momenta, $k_j = P/n - i(n-2j+1)\kappa/2$, $j = 1, 2, \dots, n$ and the energy is $E = \sum_{j=1}^n k_j^2 = P^2/n - \kappa^2 n(n^2-1)/12$. This bound state corresponds to the classical bright soliton in the $n \rightarrow \infty$ limit and may be called a quantum soliton.

To make the mathematical structure clear, it is useful to consider an operator version of an auxiliary linear problem defined on a one-dimensional lattice

$$\psi_{m+1} = L_m(\lambda)\psi_m, \quad d\psi_m/dt = M_m\psi_m, \quad (7)$$

where $L_m(\lambda)$ and M_m are $M \times M$ matrix operators, and λ is the spectral parameter. For a quantum integrable system, it is found that direct products of two L_n operators with different spectral parameters satisfy a similarity relation

$$R(\lambda, \mu)[L_n(\lambda) \otimes L_n(\mu)] = [L_n(\mu) \otimes L_n(\lambda)]R(\lambda, \mu). \quad (8)$$

Here, the symbol $\otimes$ denotes the direct product of matrices, and $R(\lambda, \mu)$, called R -matrix, is an $M^2 \times M^2$ c -number matrix. Relation (8) is the Yang–Baxter relation for a quantum system on a lattice. If the $L_n(\lambda)$ operators on different sites commute, (8) leads to

$$R(\lambda, \mu)[\mathcal{T}_N(\lambda) \otimes \mathcal{T}_N(\mu)] = [\mathcal{T}_N(\mu) \otimes \mathcal{T}_N(\lambda)]R(\lambda, \mu), \quad (9)$$

where $\mathcal{T}_N(\lambda) = L_N(\lambda)L_{N-1}(\lambda)\dots L_1(\lambda)$ is called the transition matrix or monodromy matrix. From (9), the

transfer matrix

$$T_N(\lambda) = \text{Tr} T_N(\lambda) = \sum_{i=1}^M [\mathcal{T}_N(\lambda)]_{ii}, \tag{10}$$

satisfies the commutation relation

$$[T_N(\lambda), T_N(\mu)] = 0. \tag{11}$$

Relation (11) indicates the transition matrix $T_N(\lambda)$ is a generator of conserved operators. The λ (or λ^{-1}) expansion of $T_N(\lambda)$ gives a set of conserved operators $\{I_j\}$, which are involutive, $[I_i, I_j] = 0$. In addition, commutation relations among elements of the monodromy matrix offer an algebraic formulation of the Bethe ansatz method (algebraic Bethe ansatz method).

For quantum field theoretical models, the subscript N of the operator $T_N(\lambda)$ is understood as the system size that is to be sent to infinity. Then relation (11) proves the existence of an infinite number of involutive conserved operators. It is remarkable that we may consider $L_n(\lambda)$ and $R(\lambda, \mu)$ as vertices (local Boltzmann weights) of a vertex model in statistical mechanics. In this context, the Yang–Baxter relation (8) is a sufficient condition for the commutativity of the transfer matrix in statistical mechanics. Thus, quantum integrable models in $(1+1)$ -dimension and solvable statistical models in 2-dimensions have a common property, a family of commuting transfer matrices.

Further, the quantum inverse scattering method and the Yang–Baxter relation have produced interesting developments in mathematics. Solutions of the Yang–Baxter relation with the difference property $R(\lambda, \mu) = R(\lambda - \mu)$ are classified into three classes, (i) elliptic, (ii) trigonometric, and (iii) rational functions. The trigonometric (rational) model is the critical case of the elliptic (trigonometric) model. Quantum groups and knot theory are due to the rich mathematical properties of the exactly solvable models at criticality. Extensive studies on the elliptic case are in progress.

QUANTUM NONLINEARITY

Although quantum mechanics is a linear theory, it is often used to analyze classical problems that are nonlinear. In the course of such analyses, it is interesting to consider how the nonlinear features of the classical dynamics are represented in the context of linear quantum theory, as is expected from the correspondence principle of Niels Bohr. In this entry, we see how the correspondence principle asserts itself to describe a variety of interesting nonlinear behaviors, including anharmonic oscillation, local modes, soliton binding energy, and soliton pinning.

A Nonlinear Oscillator

Consider the nonlinear mass-spring oscillator shown in Figure 1, where the spring potential is $V(x) = Kx^2/2 - \alpha x^4/4$. Under quantum theory, the oscillator energy (E) is not a continuous variable; it takes only discrete values that are eigenvalues of the time-independent Schrödinger equation

$$\left(\frac{\hbar^2}{2M}\right) \frac{d^2\psi}{dx^2} + [E - V(x)]\psi = 0, \tag{1}$$

where M is the oscillating mass and $\hbar$ is Planck's constant divided by 2π (Schiff, 1968). If α is zero, the restoring force of the spring is a linear function of its extension, and the classical oscillator of Figure 1 is linear. In this case, the energy eigenvalues are given by

$$E_n = (n + 1/2)\hbar\omega, \tag{2}$$

Figure 1. A nonlinear oscillator.

where $n=0, 1, 2, \dots$ indicates the number of quanta (called bosons) in the oscillation and $\omega = \sqrt{K/M}$ is the oscillation frequency of the classical oscillator. First derived by Erwin Schrödinger, the corresponding eigenfunctions (ψ_n) in Equation (1) are n th-order Hermite polynomials multiplied by a Gaussian factor— $\exp(-M\omega x^2/2\hbar)$ —the first few of which are shown in Figure 2 (Schrödinger, 1926). A restriction of the linear ($\alpha=0$) case is that transitions are allowed only between adjacent quantum levels. Thus, energy can only enter or leave the oscillator in quantum units of $\hbar\omega$, corresponding to Planck's radiation law.

If $\alpha \neq 0$, the classical oscillator is nonlinear, and two aspects of the quantum picture change. First, the energy eigenvalues are no longer given by the simple expression of Equation (2), and second, energetic transitions are not restricted to jumps between adjacent quantum levels. Both of these new features allow packets of energy to enter and leave the oscillator in amounts that differ from $\hbar\omega$ and, therefore, (according to Planck's law) at frequencies that differ from $\omega = \sqrt{K/M}$, in accord with observations of classical nonlinear oscillators.

In general, Equation (1) must be solved numerically to find its eigenvalues and eigenfunctions in the nonlinear case, but useful results can be obtained if the classical oscillator is considered in the rotating-wave approximation. Under this approximation, the energy eigenvalues are given by Scott (2003)

$$E_n = (\hbar\omega - \gamma/2)(n + 1/2) - \gamma n^2/2, \quad (3)$$

where $\gamma \equiv 3\alpha\hbar^2/4M^2\omega^2$, and the corresponding eigenfunctions are identical to those of the linear oscillator (as in Figure 2). Equation (3) is an example of the Birge–Sponer relation, which is widely observed for nonlinear interatomic oscillations.

To represent the quantum dynamics of an oscillator, the (linear) superposition theorem allows construction

Figure 2. Harmonic oscillator wave functions, where $y = x\sqrt{M\omega/\hbar}$.

of a wave packet of the form

$$\Psi(x, t) = \sum_{n=1}^{\infty} c_n \psi_n(x) e^{-iE_n t/\hbar}, \quad (4)$$

where the c_n are complex constants that determine the initial position of the oscillator, $\Psi(x, t)$ is a solution of the linear, time-dependent Schrödinger equation, and the probability density of finding a particular position (x) is $\int |\Psi(x, t)|^2 dx$ (Schiff, 1968).

As the mass and spring constant become larger and the total energy of the oscillator is increased, the energy difference between adjacent levels becomes an ever smaller fraction of the total energy, and the discrete energy levels (the E_n) are better approximated as a continuous function. If the c_n in Equation (4) are chosen so that Ψ is a localized wave packet, the center of mass of this packet will follow the classical nonlinear trajectory. Thus the quantum model—which is necessary for describing interatomic oscillations—merges smoothly into the classical description that we use in our daily lives.

Local Modes in Molecules

Although empirical evidence for localization of vibrational energy in molecules has been available since the 1920s, such observations have been questioned because they seem to be at variance with the predictions of quantum theory. The benzene molecule (C_6H_6), for example, is invariant under a 60° rotation about its main axis; thus eigenfunctions of the (linear) quantum theory must be similarly invariant, but a local mode of CH-stretching vibration is not (see Figure 3).

This seeming contradiction between theory and experiment can be understood by noting that a local mode is represented not by a single eigenfunction but by a wave packet of them. For a local mode of n quanta, it turns out that the energy levels lie within a range of order (Scott, 2003)

$$\Delta E \sim \frac{nE^n}{(n-1)!\gamma^{n-1}},$$

Figure 3. The planar structure of a benzene molecule, showing a local mode of the CH stretching oscillation.

where ε is the coupling energy between CH oscillations and γ is the anharmonicity as defined below Equation (3). For CH-stretching oscillations, $\varepsilon < \gamma$, so this energy range decreases very rapidly with increasing n , making the local-mode wave packet quasidegenerate at moderate quantum levels. This means that the wave packet will remain localized for times of order $\hbar/\Delta E$, which can be much longer than the time required to make an experimental observation.

Quantum Solitons

Consider next a chain (or one-dimensional lattice) of f classical nonlinear oscillators of the form

$$\left(\frac{d}{dt} - \omega\right) A_j + \varepsilon(A_{j+1} + A_{j-1}) + \gamma|A_j|^2 A_j = 0,$$

(5)

where $A_j = A_{j+f}$ is a complex amplitude and j is an index running over periodic boundary conditions. In this formulation, ω is the oscillation frequency at one of the lattice points, ε is the interaction energy between adjacent oscillators, and γ is the anharmonicity of each oscillator in the rotating wave approximation. (With $f = 6$, Equation (5) provides a model for the benzene oscillations of Figure 3.)

This discrete nonlinear Schrödinger (DNLS) equation has solitary wave solutions that approach solitons of the continuum nonlinear Schrödinger (NLS) equation as $\gamma/\varepsilon \rightarrow 0$. (Be careful not to confuse the *linear* Schrödinger equation of quantum theory in Equation (1) with Equation (5), which is a *nonlinear, classical* equation. They are quite different.) Because Equation (5) is in the rotating wave approximation, the corresponding quantum problem can be formulated and solved (Scott et al., 1994).

For two quanta ($n = 2$) in the large f limit, energy eigenvalues are arranged as in Figure 4, where each eigenfunction changes by a factor of e^{ik} under translation by one unit of j (lattice spacing); thus k is the “crystal momentum” of an eigenstate, (Haken, 1976). This figure shows both a continuum band (the shaded area) and a soliton band given by

$$\begin{aligned} E_2(k) &= \sqrt{\gamma^2 + 16\varepsilon^2 \cos^2(k/2)} \\ &= E_2(0) + k^2/2m^* + O(k^4), \end{aligned}$$

(6)

where m^* is the “effective mass” near the band center. The soliton band is characterized by two features. First, it is displaced below the continuum band by a binding energy $E_b = \sqrt{\gamma^2 + 16\varepsilon^2} - 4\varepsilon$. Second, inspection of the corresponding eigenfunctions shows that the two quanta are more likely to be on the same site for the soliton band than in the continuum band.

Figure 4. Energy eigenvalues of the DNLS equation at the second ($n = 2$) quantum level with $\varepsilon = 1$. There is one soliton band for each value of γ , which is plotted for several different values of γ .

For arbitrary n , $\gamma \ll \varepsilon$ and sufficiently large f , the quantum binding energy is

$$E_b = \frac{\gamma^2}{48\varepsilon} n(n^2 - 1),$$

(7)

which corresponds to the binding energy of a classical NLS soliton under the identification $n = \sum |A_j|^2 \gg 1$ (Makhankov, 1990).

In the classical DNLS system with $\gamma \gg \varepsilon$, numerical studies show that the soliton becomes pinned to the lattice. Under quantum theory, this classical, nonlinear phenomenon is reflected by the fact that the effective mass,

$$m^* = \frac{(n-1)! \gamma^{n-1}}{2n\varepsilon^n},$$

becomes very large. Because the classical Ablowitz–Ladik (AL) system is completely integrable for all parameter values, its soliton is not pinned for $\gamma \gg \varepsilon$. This classical fact is reflected by an effective mass that approaches zero under the same conditions. Interestingly, the Salerno equation interpolates between the DNLS and AL limits.

Quantum Representation of a Classical Soliton

Although the quantum formulation can, in principle, be used to represent a classical soliton (on an optical fiber, for example), this is a rather complex dynamical object. The closest quantum representation of a classical soliton is provided by the coherent (or Glauber) state (Makhankov, 1990), which is constructed so that the complex wave amplitude— A_j in Equation (5)—is an eigenfunction of the bosonic lowering operator. This requires a wave packet comprising components with all values of the principal quantum number (n) (Scott, 2003). For a system with f degrees of freedom, a

component at the n th level, in turn, has

$$\frac{(n + f - 1)!}{(f - 1)! n!}$$

terms, each of which is a complex construction of the eigenfunctions shown in Figure 2. (These are all of the different ways that n quanta can be placed on f freedoms.) As the number of terms at each level grows very rapidly with n , it becomes difficult to construct an exact quantum representation.

One way out of this computational dilemma is to go to the continuum approximation ($f \rightarrow \infty$) and employ the methods of quantum field theory (Lai & Haus, 1989). Another approach is to use a Hartree approximation (HA), which assumes that each boson feels the same mean-field potential as all of the other bosons (Scott, 2003). When this approximation procedure is carried through, it is found that the binding energy at the n th level is

$$E_b^{\text{HA}} = \frac{\gamma^2}{48\epsilon} n(n-1)^2, \quad (8)$$

which is less than the exact value by the factor $(n-1)/(n+1)$.

QUANTUM THEORY

Quantum theory was born in 1900 with an important paper by Max Planck on black-body radiation. In this paper, he introduced quanta of vibrational energy E which are proportional to their frequency ν , and his famous constant currently known to take the value (Mohr & Taylor, 2000)

$$\frac{E}{\nu} = h = 6.62606876(52) \cdot 10^{-34} \text{ J s.}$$

Ten years after its formulation, Planck's hypothesis had been extraordinarily successful, explaining the light spectrum of black-body radiation, the photoelectric effect, and the low-temperature reduction of heat capacity in solids.

Using Rutherford's planetary model of atoms, Niels Bohr showed in 1913 that Planck's hypothesis helps to understand the spectral lines of hydrogen by deriving their frequencies in terms of h , and the electron mass and charge. The success of Bohr's atomic model led to the formulation of the Bohr–Sommerfeld quantization rule for classically integrable systems possessing as many invariants of motion as degrees of freedom:

$$\oint p_j dq_j = h \left(n_j + \frac{\mu_j}{4} \right), \quad j = 1, 2, \dots, f,$$

where (q_j, p_j) are the canonically conjugate position-momentum variables in terms of which the system is integrable (also said separable), n_j are integers, μ_j are the so-called Maslov indices that characterize the topology of the motion (e.g., $\mu_j = 0$ for rotation, $\mu_j = 2$ for libration), and f is the number of degrees of freedom.

In 1917, Albert Einstein pointed out that the Bohr–Sommerfeld quantization rule cannot be applied to classically non-integrable systems (such as the helium atom), and it slowly became apparent that radically new ideas were required. In 1923, Louis de Broglie suggested that massive particles should behave as waves and he completed Planck's hypothesis by his famous relation, $p\lambda = h$, between the particle's momentum p and its wavelength λ .

Finally in 1925 and 1926, Werner Heisenberg and Erwin Schrödinger established quantum mechanics in two equivalent formulations. The first represents the observable quantities as matrices and the second is based on the famous Schrödinger equation

$$i \hbar \frac{\partial \psi}{\partial t} = -\frac{\hbar^2}{2m} \frac{\partial^2 \psi}{\partial \mathbf{r}^2} + V(\mathbf{r}, t) \psi, \quad (1)$$

for the wave function $\psi(\mathbf{r}, t)$ of a particle of mass m moving in the energy potential $V(\mathbf{r}, t)$, with $\hbar = h/2\pi$ and $i = \sqrt{-1}$. In 1927, Max Born proposed to interpret the square of the modulus of the wave function, $|\psi(\mathbf{r}, t)|^2$, as the probability density to observe the particle at position $\mathbf{r}$ and time t if the wave function is normalized to unity over the whole configuration space according to

$$\int |\psi(\mathbf{r}, t)|^2 d\mathbf{r} = 1. \quad (2)$$

In this formulation, physical observables are represented by linear Hermitian operators $\hat{A}$ acting on the wave function. The expectation value of an observable is given by

$$\langle A \rangle = \int \psi^*(\mathbf{r}, t) \hat{A} \psi(\mathbf{r}, t) d\mathbf{r}.$$

if the particle is in the state described by the normalized wave function ψ . The wave property prevents a quantum particle from having simultaneously well-defined position and momentum as in the classical world. This impossibility (which follows from Fourier transform theory) is expressed by Heisenberg's uncertainty relation between the uncertainties on position Δx and momentum Δp

$$\Delta x \Delta p \geq \hbar/2,$$

which finds its origin in the noncommutativity of position and momentum operators.

The normalization condition (2) has the pivotal role of selecting the physically acceptable wave functions among all the possible solutions of the Schrödinger equation (1). In particular, it is the normalization condition that leads to the quantization of energy into well-defined eigenvalues associated with the stationary states. Without the normalization condition, the wave function would present spatial instabilities that are not physically meaningful.

Because of their spatial extension, wave functions are allowed to penetrate into classically forbidden regions where the classical kinetic energy of the particle would be negative. In these regions, the normalization condition (2) forces the wave function to decrease exponentially and precludes its instability. A consequence is the phenomenon of quantum tunneling, which manifests itself in cold electronic emission or α radioactivity and finds technological applications in Leo Esaki's semiconductor tunneling diode, Ivar Giaever's superconducting tunneling diode, and the electron tunneling microscope.

Together with the normalization condition, the Schrödinger equation shares with nonlinear systems the general scheme:

$$\text{instability} \rightarrow \text{saturation} \rightarrow \text{structure}.$$

In quantum mechanics, the instability mechanism is spatial and the saturation is provided by the normalization condition that selects spatially stable wave functions such as the electronic orbitals of atoms, molecules, and solids. The selection of normalizable wave functions generates the molecular structures of stereochemistry.

However, Schrödinger's equation is linear and thus obeys the principle of linear superposition (Dirac, 1930). Accordingly, the linear combination

$$\psi = \sum_n c_n \psi_n$$

(with complex numbers c_n) is a physically acceptable solution of Equation (1). Following studies by Steven Weinberg and others (Weinberg, 1989), extremely stringent limits have been put on hypothetical nonlinear corrections to quantum mechanics. These limits have been obtained by searching for nonlinearly induced

detuning of resonant transitions between two atomic levels, putting the following upper bounds on a hypothetical nonlinear term $\Delta E(\psi, \psi^*)$ supposed to correct the right-hand side of Schrödinger Equation (1):

$$|\Delta E| < 2.4 \cdot 10^{-20} \text{ eV in } {}^9\text{Be}^+ \text{ ion} \\ (\text{Bollinger et al., 1989}),$$

$$|\Delta E| < 1.6 \cdot 10^{-20} \text{ eV in } {}^{201}\text{Hg atom} \\ (\text{Majumder et al., 1990}).$$

The principle of linear superposition of quantum mechanics has thus been confirmed by these investigations.

Nevertheless, in low-temperature many-body quantum systems, effective nonlinearities may arise if some wave function describing a subset of degrees of freedom has a feedback effect onto itself. Examples of effectively nonlinear quantum equations include the Hartree-Fock equation for fermionic systems, the Ginzburg-Landau equation for superconductors, the Gross-Pitaevskii equation for Bose-Einstein condensates, and the Ginzburg-Landau equation coupled to a Chern-Simon gauge field for the fractional quantum Hall effect.

Another problem where nonlinearities are associated with Schrödinger's equation is the theory of the optimal control of quantum systems by an external electromagnetic field. The optimal external field can be obtained as the solution of coupled nonlinear Schrödinger equations, where nonlinearity arises by a feedback mechanism of the quantum system onto itself through the external field and the desired control. Such feedback mechanisms have been experimentally implemented for laser control of chemical reactions (Rice & Zhao, 2000).

Nonlinear effects also emerge out of wave mechanics in the semiclassical limit, where the motion can be described in terms of classical orbits (solutions of nonlinear Hamiltonian equations). In the 1970s, starting from Schrödinger's equation, Gutzwiller derived a semiclassical trace formula that expresses the density of energy eigenvalues in terms of periodic orbits (Gutzwiller, 1990). The periodic orbits are unstable and proliferate exponentially in chaotic systems, where semiclassical quantization can be performed, thanks to the Gutzwiller trace formula as an alternative to the Bohr-Sommerfeld quantization rule.

In summary, nonlinear effects manifest themselves in quantum systems as phenomena emerging out of the linear wave mechanics in particular limits such as the semiclassical limit or the many-body limit at low temperature.

QUASILINEAR ANALYSIS

Analytical methods in the present-day theory of nonlinear oscillations originated in the investigations by Henri Poincaré, George D. Birkhoff, and Aleksandr Lyapunov, who laid the mathematical foundations for this theory. However, it should be noted that direct application of these mathematical methods to oscillation theory as such did not occur till much later, primarily owing to the work of Alexander Andronov (Andronov et al., 1966).

An important contribution to the development of the quantitative theory of nonlinear oscillations, especially of the applied part, was made by Balthasar van der Pol (van der Pol, 1934), who studied the operation of an electronic generator and proposed his own investigative method, namely, the method of slowly time-varying amplitudes. A rigorous justification of this method was later given by Osip Mandelshtam and N. Papaleksi (Mandelshtam & Papaleksi, 1934).

Almost independently of Mandelshtam, Andronov, and other physicists, the mathematical groundwork for nonlinear oscillation theory was laid by Nikolai Krylov, Nikolai Bogolyubov, Yuri Mitropol'sky (Krylov & Bogolyubov, 1947; Bogolyubov, 1950; Bogolyubov & Mitropol'sky, 1961; Mitropol'sky, 1971), and their disciples. They worked out the most important methods for the analysis of quasilinear oscillations: the asymptotic method, the averaging method, and the method of equivalent linearization. The last can serve as a theoretical justification of the heuristic methods of harmonic balance and statistical linearization (Landa, 1980; Pervozvansky, 1962), which are well known in mechanical and electrical engineering. Indeed, in accordance with the method of equivalent linearization, for a nonlinear function $f(x)$, we substitute a linear function λx , where λ is determined from the condition of minimization of the mean-square error

$\varepsilon = \overline{(f(x) - \lambda x)^2}$. Differentiating ε with respect to λ and equating the derivative to zero, we find

$$\lambda = \frac{\overline{f(x)x}}{\overline{x^2}}, \quad (1)$$

where over-line denote the averaging operation. Depending on the averaging technique, we obtain harmonic linearization (harmonic balance) or statistical linearization. The former takes place if we put $x = \cos \omega t$ and average the numerator and denominator of expression (1) over t for the period $T = 2\pi/\omega$. The latter takes place if we suppose x to be distributed according to a certain probability distribution (for example, Gaussian) and find the statistical average.

The van der Pol method, or the method of slowly time-varying amplitudes, is applicable to near-linear, near-conservative self-oscillatory systems. The method was suggested by van der Pol as applied to self-oscillatory systems with one degree of freedom. However, the method may be easily generalized to self-oscillatory systems with n degrees of freedom, which are described by equations of the form

$$\ddot{y}_k + \omega_k^2 y_k = \mu Y_k(t, y, \dot{y}) \quad (k = 1, 2, \dots, n), \quad (2)$$

where μ is a small parameter, $y = \{y_1, \dots, y_n\}$, $\dot{y} = \{\dot{y}_1, \dots, \dot{y}_n\}$. For $\mu = 0$, Equations (2) are the equations of a linear oscillatory system with n degrees of freedom written in terms of normal coordinates.

As mentioned above, a rigorous justification of the van der Pol method was given by Mandelshtam and Papaleksi (Mandelshtam & Papaleksi, 1934). They showed that the truncated van der Pol equations can be found by averaging the initial equations over "fast time" for the period $T = 2\pi/\omega$. By doing so, Mandelshtam and Papaleksi pioneered the averaging method, the rigorous theory of which was worked out by Bogolyubov (1950) and developed by Mitropol'sky (1971). This theory concerns so-called equations in a standard form. By means of a certain change of variables, any equations describing oscillations in near-conservative systems can be reduced to equations in a standard form. More general theory is related to systems incorporating fast and slow variables (Volosov & Morgunov, 1971; Vasilyeva & Butuzov, 1990). In particular, this theory is used for analysis of relaxation oscillators (Mischenko & Rozov, 1975).

The asymptotic Krylov–Bogolyubov method is conceptually a generalization of the van der Pol method that allows us to calculate the higher approximations. The method has two modifications, depending on the form of the original equations and on the problem in question (Landa, 1980). If we are interested in the calculation of multi-frequency oscillations, we conveniently set the equations in the form of (2).

Provided we are interested in the calculation of single-frequency oscillations, we can set the original equations in the following form:

$$\dot{\mathbf{y}} + \mathcal{B}\mathbf{y} = \mu \mathbf{Y}(t, \mathbf{y}), \quad (3)$$

where $\mathbf{y}$ is a vector with n components, $\mathcal{B}$ is a square matrix with elements b_{jk} , μ is a small parameter, and $\mathbf{Y}(t, \mathbf{y})$ is a nonlinear vector function of time and of all components of the vector $\mathbf{y}$. We assume that for $\mu = 0$, Equations (3) describe a linear conservative system.

First, we consider the case when the original equations of a system are set in the form of (2). For $\mu \neq 0$, let us represent a solution of Equations (2) as a power series in μ :

$$\begin{aligned} y_k &= y_k^{(0)} + \mu u_{1k}(A, \psi, \mu t) \\ &\quad + \mu^2 u_{2k}(A, \psi, \mu t) + \dots, \end{aligned} \quad (4)$$

where $y_k^{(0)} = A_k \cos \psi_k$, $\psi_k = \omega_k t + \varphi_k$, A_k and φ_k are slowly time-varying functions obeying the equations

$$\frac{dA_k}{dt} = \mu f_{1k}(A, \varphi, \mu t) + \mu^2 f_{1k}(A, \varphi, \mu t) + \dots, \quad (5)$$

$$\frac{d\varphi_k}{dt} = \mu F_{1k}(A, \varphi, \mu t) + \mu^2 F_{1k}(A, \varphi, \mu t) + \dots$$

Here $u_{1k}(A, \psi, \mu t)$, $u_{2k}(A, \psi, \mu t)$, ... and $f_{1k}(A, \psi, \mu t)$, $f_{2k}(A, \psi, \mu t)$, ..., $F_{1k}(A, \psi, \mu t)$, $F_{2k}(A, \psi, \mu t)$, ... are unknown functions, which should be found.

Demanding the absence of resonant constituents in functions u_{1k} , we find the unknown functions f_{1k} and F_{1k} :

$$\begin{aligned} f_{1k} &= -\frac{1}{2\omega_k} X_{1k}(\mu t, A, \varphi), \\ F_{1k} &= -\frac{1}{2\omega_k A_k} Z_{1k}(\mu t, A, \varphi). \end{aligned} \quad (6)$$

Thus, we obtain the equations of the first approximation for the amplitudes and phases:

$$\begin{aligned} \frac{dA_k}{dt} &= -\frac{\mu}{2\omega_k} X_{1k}(\mu t, A, \varphi), \\ \frac{d\varphi_k}{dt} &= -\frac{\mu}{2\omega_k A_k} Z_{1k}(\mu t, A, \varphi). \end{aligned} \quad (7)$$

These equations coincide with those found by using the van der Pol method. The functions u_{1k} describe the higher harmonics and combination frequencies in the solution of the first approximation.

Using the next terms in the expansions found above, we can obtain the equations of the second and higher approximations.

Let us consider further the case when the original equations of a system are set in the form of (3) and we are interested in finding single-frequency oscillations described by

$$\mathbf{y} = A(\mathbf{V}e^{i(\omega t + \varphi)} + \text{c.c.}), \quad (8)$$

where ω is one of the system fundamental frequencies, $\mathbf{V}$ is the eigenvector of the matrix $\mathcal{B}$ corresponding to the frequency ω , and c.c. means the complex conjugate value.

Using the procedure of the method described, we obtain the equations for the unknown vector functions k_j :

$$\begin{aligned} \omega \frac{\partial k_1}{\partial \psi} + \mathcal{B}k_1 &= -f_1(\mathbf{V}e^{i\psi} + \text{c.c.}) \\ &\quad -iA F_1(\mathbf{V}e^{i\psi} - \text{c.c.}) + Y_1, \dots \end{aligned} \quad (9)$$

Let us further expand the vector functions $k_1, k_2, \dots, Y_1, Y_2, \dots$ into the Fourier series with slowly time-varying coefficients:

$$\begin{aligned} k_j(A, \psi, \mu t) &= \sum_{k=-\infty}^{\infty} U_j^{(k)}(A, \varphi, \mu t) e^{ik\psi}, \\ Y_j(A, \psi, \mu t) &= \sum_{k=-\infty}^{\infty} Y_j^{(k)}(A, \varphi, \mu t) e^{ik\psi}. \end{aligned} \quad (10)$$

Substituting (10) into (9) and equating the coefficients of the same harmonics, we obtain, for each j , a system of non-uniform equations for the components of the vector functions $U_j^{(k)}$. For $k \neq 1$, the determinant of this system is nonzero, and hence, all of $U_j^{(k \neq 1)}$ can be determined uniquely. For $k = 1$, the system determinant is zero. In this case we should require, for all j , the fulfillment of the compatibility conditions $\mathcal{A}R_j = 0$, where R_j is the right-hand side of the j th system and $\mathcal{A}$ is the adjoint matrix. These conditions allow us to find $f_1(A, \varphi, \mu t)$, $F_1(A, \varphi, \mu t)$, $f_2(A, \varphi, \mu t)$, $F_2(A, \varphi, \mu t)$, ...

Let us consider the first approximation. From (9) and (10) we obtain the following equation for the vector function $U_1^{(k)}$:

$$(ik\omega\mathcal{E} + \mathcal{B})U_1^{(k)} = -(f_1 + iA F_1)\delta_{k1}\mathbf{V} + Y_1^{(k)}, \quad (11)$$

where $\mathcal{E}$ is an identity matrix and δ_{k1} is the Kronecker delta. For $k = 1$, the compatibility condition of system (11) is

$$-f_1 A \mathbf{V} - iA F_1 A \mathbf{V} + \mathcal{A} Y_1^{(1)} = 0. \quad (12)$$

Splitting the real part and the imaginary part in Equation (12) we find

$$\begin{aligned} f_1(A, \varphi, \mu t) &= \text{Re} \left\{ \frac{1}{\text{Sp } \mathcal{A}} \sum_j \frac{A_{jj}}{V_j} Y_{1j}^{(1)}(A, \varphi, \mu t) \right\}, \\ F_1(A, \varphi, \mu t) &= \frac{1}{A} \text{Im} \left\{ \frac{1}{\text{Sp } \mathcal{A}} \sum_j \frac{A_{jj}}{V_j} Y_{1j}^{(1)}(A, \varphi, \mu t) \right\}, \end{aligned} \quad (13)$$

where $\text{Sp } \mathcal{A}$ is the spur of the matrix $\mathcal{A}$.

The second and higher approximations can be found in much the same way.

QUASIPERIODICITY

The term *quasi-periodicity* implies a type of motion that is regular (nonchaotic) but consists of a combination of periodic motions with a trajectory that—after sufficient time—passes arbitrarily close to an earlier value.

For flow systems, a trajectory $x(t) \in \mathbb{R}^n$ is called *k*-quasi-periodic if it can be written in the form

$$x(t) = f(\omega_1 t, \dots, \omega_k t).$$

Here f is a smooth nonlinear function of period 2π in each of its k arguments separately. The function f belongs to a class of almost periodic functions

Figure 1. Schematic diagram of motion on the T^2 (two-dimensional) torus and the Poincaré cross section.

if frequencies $\omega_1, \dots, \omega_k$ are not rationally related (are incommensurate); that is, $\sum_1^k l_i \omega_i \neq 0$ when $l_1, \dots, l_k \in \mathbb{Z}$ and $\sum_1^k |l_i| > 0$ (Levitant & Zhikov, 1982). In other words, the ratio between two frequencies ω_i and ω_j , $i \neq j$ is irrational:

$$\frac{\omega_i}{\omega_j} \neq \frac{p}{q}, \quad p \in \mathbb{Z}, \quad q \in \mathbb{Z}. \quad (1)$$

A quasi-periodic trajectory lies on a k -dimensional torus (T^k), which can be an attractor, a repeller, or a saddle of a dynamic system. The term *quasi-periodicity* describes motion on the 2-dimensional torus (T^2) whereas *k-quasi-periodicity* is used for motion on tori of larger dimension. A two-dimensional closed surface in phase space corresponds to the two-dimensional torus T^2 , and asymptotically (as $t \rightarrow \infty$), the trajectory covers its entire surface.

To describe quasi-periodic motion, it is convenient to use a Poincaré cross section (Figure 1) or a map. The T^2 torus is given by a closed invariant curve in Poincaré cross section. Maps are widely used in practice to investigate the properties of quasi-periodic motion. A typical map that serves for this purpose, as well as for investigation of the transition from quasi-periodicity to chaos, is the circle map:

$$\theta_{n+1} = \theta_n + \Omega - \frac{K}{2\pi} \sin 2\pi\theta_n, \quad \text{mod } 1. \quad (2)$$

Here θ is a phase angle defined in the interval $[0; 1]$, while $\Omega \in [0; 1]$ and $K \geq 0$ are parameters of the map. Map (2) for $K < 1$ describes the dynamics of a non-autonomous self-oscillating system, for example, the van der Pol oscillator under external periodic forcing. The variable θ in this case represents the phase difference between the self-oscillations and the external force, the parameter Ω corresponds to the mismatch between the forcing frequency and the natural frequency of the oscillator, and the parameter K corresponds to the forcing amplitude.

A number of problems arise during numerical simulations and experimental investigations of attractors in quasi-periodic systems. First, it is impossible to

simulate an irrational ratio in Equation (1) because each number stored in a computer is limited to a finite set of digits. Second, as a consequence of the measurement error in experimental investigations, it is, in practice, impossible to determinate reliably whether a frequency ratio is rational or irrational. Third, because the presence of noise in real systems leads to a smearing of the system's characteristics, it is possible to interpret experimental results wrongly. Thus, if a calculated invariant curve in a Poincaré cross section is smeared (has a finite width), then a noisy quasi-periodic motion can become entangled with chaos.

To obtain reliable information about the type of motion, it is necessary to use a set of characteristics such as the spectrum of Lyapunov exponents (SLE), a power spectrum, an autocorrelation function (ACF), or the smoothness of the invariant curve in the Poincaré cross section. In quasi-periodic motion, the SLE has no positive values, and the number of zeros is equal to the number of incommensurate base frequencies defined by the quasi-periodic motion. For example, the T^2 torus of a dissipative system is characterized by two Lyapunov exponents that are zero and others that are negative. The SLE of chaotic behavior includes at least one positive value. The power spectrum of quasi-periodic motion is discrete and consists of peaks at frequencies $n\omega_1 \pm m\omega_2$, with n and m taking arbitrary integer values. In reality, the peaks need not be mathematically sharp, but can be instrumentally sharp. The spectrum of a chaotic motion, on the other hand, is continuous and consists of an infinite number of base functions and their combinations. The ACF of a trajectory on a torus is an infinitely oscillating function that does not fall to zero as $t \rightarrow \infty$; in contrast, the ACF of a chaotic trajectory tends to zero as $t \rightarrow \infty$. In Poincaré cross section, a smooth curve corresponds to a torus, whereas a chaotic regime is characterized by a fractal structure.

Quasi-periodic motion can be observed in conservative and dissipative systems characterized by two or more incommensurate frequencies generated by the system and/or external sources (Glazier & Libchaber, 1988). The transition from a stationary state to quasi-periodic motion is realized as the result of at least two consecutive Hopf bifurcations, which add two incommensurate frequencies to the system, hence giving rise to a T^2 torus. Further Hopf bifurcations lead to a torus of larger dimension. Landau (1965) conjectured that turbulence arises through an infinite series of such Hopf bifurcations, increasing the degree of quasi-periodicity step-by-step up to infinity.

The possibility of such a scenario is problematic because the Kolmogorov–Arnol'd–Moser (KAM) theorem and the results of Newhouse et al. (1979) show that T^k tori can be structurally unstable when $k \geq 3$. This instability is found to increase with nonlinearity, which can lead to synchronization if an irrational frequency ratio becomes rational, or can transform a low-

dimensional torus to chaos. However, there are also models (Ott, 2002) and experiments (Gollub & Benson, 1980), which prove that the tori T^k still exist for $k \geq 3$. The flow of blood through the cardiovascular system seems to be an example of dynamics characterized by a hypertorus, with $k \geq 3$ (Stefanovska & Bračič, 1999).

Several scenarios of transition from quasi-periodicity to chaos are known. The transition from T^2 to a strange chaotic attractor has been thoroughly investigated (Afraimovich & Shilnikov, 1991; Anishchenko et al., 2002). First, the torus loses smoothness, and then stable and saddle resonances (cycles corresponding to a rational frequency ratio) arise on the torus. Nonlocal bifurcations (homoclinic tangencies of manifolds) of these saddles lead to chaos later on.

A similar scenario is also observed for the T^3 torus (Anishchenko et al., 2002). The occurrence of torus doublings can precede the appearance of resonances on the torus: a finite number of bifurcations occur, after which the torus is destroyed as described above. The possible reality of an infinite series of torus doubling bifurcations (the Feigenbaum scenario of the transition to chaos) remains an open question, although renormalization group analysis (Feigenbaum et al., 1982) allows such a possibility theoretically.

Newhouse et al. (1979) have shown that small perturbations of the T^3 torus can lead to a strange chaotic attractor on the torus. Bifurcations, which lead from the torus to chaos, have not yet been studied in detail, but investigations indicate that the transition is connected with the appearance and destruction of resonances on the torus. Furthermore, the transition from T^3 to chaos has been observed only in maps, and the possibility of its realization in flow systems remains unclear.

A third scenario is the transition from quasi-periodicity to a nonstrange chaotic attractor (Arnol'd, 1983). If a chaotic attractor on T^3 covers all the surface of the torus, then the capacity of the attractor is integer and the largest Lyapunov exponent is positive.

Another way in which the transition from quasi-periodicity to chaos can occur is through the appearance of a strange nonchaotic attractor (SNA), which has a fractal structure and no positive values in the SLE (Grebogi et al., 1984). Such an evolution is observed in systems under external quasi-periodic forcing that drives the system with an irrational frequency ratio, which does not depend on parameters and properties of the system itself. The bifurcation mechanisms involved in the transition from torus to SNA, and the subsequent transition from SNA to chaos, are subjects of active investigation.

RANDOM MATRIX THEORY I: ORIGINS AND PHYSICAL APPLICATIONS

The textbook examples of quantum systems typically have a complete set of quantum numbers. For hydrogen-like atoms in a weak magnetic field, the set of radial, angular, and magnetic quantum numbers, together perhaps with the spin state, uniquely determines the energy levels of the atom. Nuclear physicists were among the first to encounter a situation where this is not possible. Scattering protons and neutrons off nuclei revealed a huge number of resonances that could no longer be completely labelled by their quantum numbers. In view of this fact and the uncertainty in the detailed interaction between the neutrons, Eugene Wigner advanced a statistical approach to the observed spectra: instead of trying to characterize each resonance individually, he proposed to look for a statistical description of their distribution and their strengths (see Wigner (1967) for an account of the early developments). Typical quantities of interest are then the mean density of resonances, probabilities for their spacings, the two- or more point correlation functions, and the distribution of transition strengths. The Hamiltonian was modeled as a random matrix, and by ingenious mathematical techniques a complete characterization of the spectral properties of certain ensembles of random matrices could be achieved. Wigner's John von Neumann lecture (Wigner, 1967), and the books by Mehta (1991) and Porter (1965) survey many of the results and methods. These sources also contain references to work in mathematics before the widespread use of random matrices in physics.

The most important ensembles are the Gaussian ones. Consider ensembles of $N \times N$ matrices H with statistically independent real or complex entries and a

distribution function

$$P_N(H_{11}, H_{12}, \dots, H_{NN}) = \prod_{i,j} p_{ij}(H_{ij}). \quad (1)$$

It is natural to demand invariance of the distribution under transformation of bases, since none of them can be singled out a priori. If the allowed transformations are orthogonal, unitary, or symplectic, the Gaussian orthogonal ensemble (GOE), Gaussian unitary ensemble (GUE), or the Gaussian symplectic ensemble (GSE) is obtained, respectively. The distribution functions are

$$P_{N,\beta} = \left(\frac{\beta}{2\pi}\right)^{N/2} \left(\frac{\beta}{\pi}\right)^{\beta N(N-1)/2} \exp\left(-\frac{\beta}{2} \text{tr } H^2\right) \quad (2)$$

with the parameters $\beta = 1$ for GOE, $\beta = 2$ for GUE, and $\beta = 4$ for GSE.

Of the many quantities that can be studied and for which in many cases exact results can be obtained, we list only two: the level spacing distribution and the number variance (Figure 1). For others, see Brody et al. (1981), Guhr et al. (1998), Haake (2001), Mehta (1967), and Stöckmann (1999).

The level spacing distribution is the probability density to find two neighboring levels a distance s apart (in units of the mean level spacing). The expression that results from the random matrix ensembles is somewhat involved, but a very good approximation was given by Wigner:

$$P_{\text{GOE}} = \frac{\pi}{2} s e^{-(\pi/4)s^2}, \quad (3)$$

$$P_{\text{GUE}} = \frac{32}{\pi^2} s^2 e^{-(4/\pi)s^2}, \quad (4)$$

$$P_{\text{GSE}} = \frac{2^{18}}{3^6 \pi^3} s^4 e^{-(64/9\pi)s^2}. \quad (5)$$

The characteristic feature of these expression is that for small s the distribution increases like s^β , so that small spacings are suppressed.

The number variance measures the deviation between the true and the expected number of eigenvalues in an interval. In units of the mean spacing

Figure 1. Level spacing distribution and number variance for the different ensembles.

the expected number equals the length L of the interval, and with $N(L)$ the true number, variance is

$$\Sigma^2(L) = \langle (N(L) - L)^2 \rangle = \langle (N(L))^2 \rangle - L^2. \quad (6)$$

In a Poisson process for uncorrelated levels, the number variance will increase linearly, $\Sigma^2(L) = L$. In the random matrix ensembles, the increase is slower,

$$\Sigma^2(L) \sim \frac{2}{\beta\pi^2} \ln L + c_\beta \quad (7)$$

with constants c_β (for complete expressions, see, for example, Brody et al. (1981)). The slow logarithmic increase reflects the interactions between levels.

Between about 1975 and the mid-1980s, Michael Berry, Oriol Bohigas, and others applied such statistical measures to systems with a chaotic classical limit and observed level distributions and correlators in agreement with random matrix theory. They conjectured that chaotic systems will show random matrix behavior consistent with the global real symmetric, complex Hermitian, or symplectic symmetry of the Hamiltonian. The eigenvalue distribution for integrable systems, as shown earlier by Berry and Tabor, should show Poissonian statistics (Haake, 2001; Stöckmann, 1999). The argument for the two situations is roughly as follows: if the classical system is integrable, the quantum eigenstates are localized on tori and the energies can be approximated by Bohr–Sommerfeld quantization of the appropriate actions. Different tori give independent sequences of quantum eigenvalues, so that the collection of eigenvalues reflects a random appearance of eigenvalues, without correlations. As a result, the distribution of mean level spacings becomes exponential. In a chaotic system the eigenstates are spread over the con-

nected chaotic components. They thus have the same support, but since they have to be orthogonal, they have to interact. This interaction then leads to level repulsion and the observed suppression of small spacings in $P(s)$. The conjecture is supported by semiclassical arguments for the two-point correlation function (Berry, 1985) and a large body of empirical evidence from experimental data for nuclei, atoms, and molecules and from numerical data for various systems (Stöckmann, 1999). The few exceptions (as, for instance, the arithmetical billiards on surfaces of negative curvature (Bogomolny et al., 1997)) have led to clarifications of the necessary requirements. But so far no proof has emerged, neither for integrable nor for chaotic systems.

The connection between random matrices and the chaotic behavior of the underlying wave behavior indicates why random matrix statistics should also appear in many nonquantum situations. Indeed, acoustic resonances in irregularly shaped containers, electromagnetic resonances in cavities, and mechanical vibrations of plates and other solid blocks all show statistical properties in good agreement with random matrix theory expectations when the short wavelength dynamics of wave fronts is chaotic (Stöckmann, 1999).

The statistical measures developed within random matrix theory have propagated into other fields as well, most notably into the theory of the Riemann zeta function. The Riemann zeta function as defined by

$$\zeta_R(s) = \sum_{n=1}^{\infty} n^{-s} \quad (8)$$

can be analytically continued into the complex plane. It then has a pole at $s=1$ and so-called trivial zeroes at $s=-2, -4, \dots$. Bernhard Riemann's long-standing conjecture is that all its other zeroes lie along the line $s = \frac{1}{2} + ir$. David Hilbert proposed to identify an eigenvalue problem that has these zeroes as eigenvalues. While that system is still elusive, analysis of the statistics suggests that it belongs to the universality class of the Gaussian unitary ensemble (see Berry & Keating (2000) for an account of the fascinating relations between random matrix theory, primes, and the statistics of the Riemann zeroes).

While all previous examples dealt with individual systems having a fixed Hamiltonian, one can also consider disordered systems, where as an additional statistical element, certain variations in the Hamiltonian enter. For instance, in a solid the mean density of impurities can be controlled experimentally, but the detailed positions and their effects on a specific experiment are difficult to fix. It is then possible to again set up random matrix models and to derive measurable quantities that are universal in that they depend on the global symmetry of the system only, see Beenakker (1997), Guhr et al. (1998), and Efetov (1997).

Through the connection to disordered systems, techniques from field theory, Grassmann algebras, and supersymmetry entered random matrix theory (Zirnbauer, 1996). Those tools allow analytical calculations of many quantities both in the extreme quantum limit and in the semiclassical limit. More importantly, they have indicated a link to group theory and homogeneous spaces. The classification into three universality classes (GOE, GUE, and GSE) above has to be extended to a total of 10 cases. The realizations of the other cases require additional symmetries. Three cases can be found by extending the three classical ensembles to Dirac Hamiltonians with a particle-hole symmetry. Examples for the remaining four can be found in certain normal-superconducting systems.

As suggested in the introduction to Guhr et al. (1998), the field of random matrices has opened up a new class of stochastic systems with a wide range of applications in physics and elsewhere and with intriguing mathematical connections. The unifying feature is that stochasticity combined with general symmetries leads to universal laws not based on dynamical principles. Indications are that it can also play a role in the analysis of financial data, in wireless communications, or in extracting correlations in neural signals (see, e.g., Forrester et al., 2003).

RANDOM MATRIX THEORY II: ALGEBRAIC DEVELOPMENTS

It was hypothesized by Eugene Wigner in the 1950s that the highly excited states of complex nuclei would have the same statistical properties as the eigenvalues of a large random real symmetric matrix. In pure mathematics, one finds a random matrix hypothesis in the theory of the celebrated Riemann hypothesis. Thus the Montgomery–Odlyzko law states that the statistics of the large zeros of the Riemann zeta function on the critical line (Riemann zeros) coincide with the statistics of the eigenvalues of a large complex Hermitian matrix. To test such hypotheses (for definiteness, the Montgomery–Odlyzko law), one computes a large sequence of consecutive Riemann zeros, scales the sequence so that locally the mean spacing is unity, and then empirically computes statistical quantities. A typical example of the latter is the distribution of the spacing between consecutive zeros. This must be compared against the same statistical quantity for the eigenvalues of large random complex Hermitian matrices. How then does one compute the eigenvalue spacing distribution for random matrices?

Hermitian random matrices with real, complex, and quaternion real Gaussian elements form matrix ensembles referred to as the Gaussian orthogonal ensemble (GOE) ($\beta = 1$), the Gaussian unitary ensemble (GUE) ($\beta = 2$), and the Gaussian symplectic ensemble (GSE) ($\beta = 4$), respectively, where β is a convenient label. Consider the bulk eigenvalues of such large matrices, scaled to have unit density. Denote by $p_\beta(k; s)$ the probability density that there are exactly k eigenvalues in between two eigenvalues of spacing s , and denote by $E_\beta(k; s)$ the probability that there are exactly k eigenvalues in an interval of size s . Define the generating functions $p_\beta(s; \xi) = \sum_{k=0}^{\infty} (1 - \xi)^k p_\beta(k; s)$ and $E_\beta(s; \xi) = \sum_{k=0}^{\infty} (1 - \xi)^k E_\beta(k; s)$. Note from the definitions that these quantities are related by $p_\beta(s; \xi) = \frac{1}{\xi^2} \frac{d^2}{ds^2} E_\beta(s; \xi)$.

Gaudin observed that the determinantal form of the correlations in the case $\beta = 2$ allows $E_2(s; \xi)$ to be written as a Fredholm determinant,

$$E_2(s; \xi) = \det(1 - \xi K_2) \\ = \det(1 - \xi K_2^+) \det(1 - \xi K_2^-), \quad (1)$$

where K_2 , $K_2^\pm$ are integral operators on $(0, s)$ with kernels

$$\frac{\sin \pi(x - y)}{\pi(x - y)},$$

and

$$\frac{1}{2} \left[\frac{\sin \pi(x-y)}{\pi(x-y)} \pm \frac{\sin \pi(x+y)}{\pi(x+y)} \right],$$

respectively. The second equality is noted in (1) because both factors therein are related to E_1 . Thus, with $E_1(-1; s) = 0$, define

$$E_1^\pm(s; \xi) = \sum_{n=0}^{\infty} (1-\xi)^n \left(E_1(2n; s) + E_1(2n \mp 1; s) \right).$$

Then an inter-relationship between large GOE and large GUE matrices due to Dyson implies

$$E_2(s; \xi) = E_1^+(s; \xi) E_1^-(s; \xi).$$

This factorization turns out to be the same as in (1), so one obtains Mehta's result

$$E_1^\pm(s; \xi) = \det(1 - \xi K_2^\pm).$$

For the case $\beta = 4$, one uses Mehta's and Dyson's inter-relationship between large GSE matrices and large GOE matrices to conclude

$$E_4(n; s) = E_1(2n; 2s) + \frac{1}{2} \left(E_1(2n-1; 2s) + E_1(2n+1; 2s) \right).$$

A new line of study of E_β was initiated by Jimbo, Miwa, Mōri, and Sato in 1980, which related the Fredholm determinant in (1) to integrable systems theory, resulting in the formula

$$E_2(s; \xi) = \exp \int_0^{\pi s} \sigma(t; \xi) \frac{dt}{t},$$

where σ satisfies a particular example of the σ -form of the Painlevé V equation,

$$(s\sigma'')^2 + 4(s\sigma' - \sigma)(s\sigma' - \sigma + (\sigma')^2) = 0,$$

$$\sigma(s; \xi) \underset{s \rightarrow 0}{\sim} -\frac{\xi s}{\pi} - \left(\frac{\xi s}{\pi} \right)^2.$$

The quantities $E_1^\pm$ can also be expressed in terms of Painlevé transcendents. Thus, combining results of the present author with results of Tracy and Widom, one has

$$E_1^\pm(s; \xi) = \exp \int_0^{(\pi s/2)^2} v(t; \xi; a) \frac{dt}{t} \Big|_{a=\pm 1/2},$$

where $v(t; \xi; a)$ satisfies a particular example of the σ -form of the Painlevé III' equation

$$(tv'')^2 - a^2(v')^2 - v'(4v' + 1)(v - tv') = 0,$$

$$v(t; \xi; a) \underset{t \rightarrow 0}{\sim} -\frac{\xi t^{a+1}}{2^{2a+2} \Gamma(a+1) \Gamma(a+2)}.$$

Another bulk spacing distribution with a Painlevé type evaluation is the nearest-neighbor spacing between

Figure 1. Comparison of $nn(t)$ for the GUE (continuous curve) and for 10^6 consecutive Riemann zeros, starting near zero number 1 (open circles), 10^6 (asterisks), and 10^{20} (filled circles).

eigenvalues (i.e., the minimum of the distances to the left neighbor and the right neighbor) for large GUE matrices, $nn(t)$ say. Forrester and Odlyzko (1996) have shown that

$$nn(t) = -\frac{y(2\pi t; a)}{t} \exp \int_0^{\pi t} \frac{y(2s; a)}{s} ds \Big|_{a=1},$$

where $y(s; a)$ satisfies the differential equation

$$(sy'')^2 + 4(-a^2 + sy' - y)(y')^2 - \{a - (a^2 - sy' + y)^{1/2}\}^2 = 0$$

subject to the boundary condition

$$y(s; a) \underset{s \rightarrow 0}{\sim} -\frac{2(s/4)^{2a+1}}{\Gamma(1/2 + a)\Gamma(3/2 + a)}.$$

Comparison of a plot of this statistic, obtained from the formula in Forrester and Odlyzko (1996), against the same statistic computed, empirically for large sequences of Riemann zeros starting at three different positions along the critical line is given in Figure 1.

RANDOM MATRIX THEORY III: COMBINATORICS

As the two previous entries show, random matrix theory (RMT) is a field of research devoted to the statistical analysis of the eigenvalues of matrices selected at random from a given set of matrices (Mehta, 1991). Recently there have been surprising discoveries that connect RMT to a branch of mathematics called combinatorics.

One fundamental topic within combinatorics is the study of permutations. A permutation is a rearrangement of the elements of a set. The set is usually finite, in which case it may be taken to be the first n positive integers, and a permutation may also be represented as a one-to-one invertible mapping from $\{1, 2, \dots, n\}$ into itself. For each positive integer n , the number of permutations of length n is $n!$. If permutations of length n are selected at random, and each permutation is equally likely, then the probability of selecting a particular permutation is $1/n!$. In thinking about permutations probabilistically, researchers have discovered new connections to random matrix theory.

Random Matrix Theory: Gaussian Unitary Ensemble

The Gaussian unitary ensemble (GUE) is a fundamental example of a RMT. The collection of matrices is all Hermitian (self-adjoint, complex) matrices of size n . The diagonal matrix entries M_{jj} , $j = 1, 2, \dots, n$, are independent normal random variables; that is, each has probability measure $\frac{1}{\sqrt{2\pi}} e^{-m^2/2} dm$. The off-diagonal matrix entries $M_{jk} = M_{jk}^{(R)} + iM_{jk}^{(I)}$, $1 \leq j \neq k \leq n$, are complex, and $\{M_{jk}^{(R)}, M_{jk}^{(I)}\}_{1 \leq j < k \leq n}$ is a collection of independent identically distributed Gaussian random variables with probability measure $\frac{1}{\sqrt{\pi}} e^{-m^2} dm$. The matrix entries below the diagonal are determined by the entries above the diagonal because the matrices satisfy the self-adjointness criterion $M^* = M$, where $(M^*)_{jk} = \overline{M_{jk}}$ and $\overline{(\cdot)}$ represents the complex conjugate of $(\cdot)$. Thus, the GUE of random matrices is merely a probability measure defined on the standard Euclidean space of dimension n^2 . In standard probability terminology, the probability of finding a matrix in an “infinitesimal volume element” of matrices centered at a given matrix $M = (M_{jk})_{1 \leq j, k \leq n}$ is

$$\frac{1}{2^n \pi^{n^2}} e^{-\frac{1}{2} \sum_{j=1}^n M_{jj}^2 - \sum_{j=1}^{n-1} \sum_{k=j+1}^n (M_{jk}^{(R)})^2 + (M_{jk}^{(I)})^2} \\ \times \prod_{j=1}^n dM_{jj} \prod_{1 \leq j < k \leq n} dM_{jk}^R dM_{jk}^I.$$

This is often more conveniently written in the form

$$\frac{1}{Z_n} e^{-\frac{1}{2} \text{Tr}(M^2)} dM, \quad (1)$$

where $Z_n = 2^n \pi^{n^2}$, $dM = \prod dM_{jj} \prod dM_{jk}^{(I)} dM_{jk}^{(R)}$, and $\text{Tr}(A)$ represents the trace of the matrix A , $\text{Tr}(A) = \sum_{j=1}^n A_{jj}$.

This is just one example of an RMT. For example, one may replace $\text{Tr}(M^2)$ in (1) by $\text{Tr}(M')$, or $\text{Tr}(V(M))$ for any reasonable function $V: \mathbb{R} \rightarrow \mathbb{R}$.

The eigenvalues $\lambda_1 \leq \lambda_2 \leq \dots \leq \lambda_n$ of a matrix M selected at random according to (1) are fundamental random variables, and quite a lot is known about their statistical properties. One example is the largest eigenvalue λ_N . Because of many different applications, their statistical behavior is particularly interesting when n goes to ∞ . This random variable's behavior when $n \rightarrow \infty$ is as follows:

$$\lim_{n \rightarrow \infty} \text{Prob} \left(\lambda_n < \sqrt{2n} + \frac{s}{\sqrt{2n}^{1/6}} \right) = F(s),$$

where

$$F(s) = \exp \left(- \int_s^\infty (x-s)^2 q(x) dx \right) \quad (2)$$

and q is the unique solution to the Painlevé II equation

$$q'' = sq + 2q^3$$

satisfying the condition

$$q(s) \sim \text{Ai}(s) \quad \text{as } s \rightarrow \infty.$$

This result is due to Craig Tracy and Harold Widom (1994), and the function F is often referred to as the Tracy–Widom distribution. Surprisingly, the Painlevé equation appears in a fundamental way in random matrix theory. It also appears, in an equally fundamental way, in combinatorics.

Increasing Subsequences of Permutations

A permutation, or an invertible mapping from the set $\{1, 2, \dots, n\}$ to itself may be represented as a sequence of numbers. For example, the sequence 3, 1, 2 represents the permutation $\sigma(1) = 3$, $\sigma(2) = 1$, $\sigma(3) = 2$. An increasing subsequence of a permutation is obtained by representing a permutation as a sequence, and then selecting a subsequence in which the elements are increasing. For example, the sequence 1, 2 is an increasing subsequence of the permutation σ considered above.

Each permutation has many increasing subsequences. In combinatorics the length of the largest increasing subsequence of a permutation is an important object of study. For the permutation σ considered above, that length is 2. As another example, if π is

the permutation 1,3,2,4,5, that is, $\pi(1)=1$, $\pi(2)=3$, $\pi(3)=2$, $\pi(4)=4$, $\pi(5)=5$, the length of π 's longest increasing subsequence is 4. If σ is a permutation of length n , then $\ell_n(\sigma)$ denotes the length of σ 's longest increasing subsequence.

If permutations of length n are selected at random, and each permutation has equal probability $1/n!$, then $\ell_n(\sigma)$ is a natural random variable arising from combinatorics. Its statistical behavior for n large has been an object of study since at least the 1960s. Interest in ℓ_n stems from basic connections between permutations and games of chance, such as "solitaire," also known as "patience sorting." In their mathematical review, Aldous & Diaconis (1999) give a precise description of such a game:

Take a deck of cards labeled 1, 2, 3, $\dots$, n . The deck is shuffled, cards are turned up one at a time and dealt into piles on the table, according to the rule

- A low card may be placed on a higher card (e.g., 2 may be placed on 7) or may be put into a new pile to the right of the existing piles.

At each stage we see the top card on each pile. If the turned up card is higher than the cards showing then it must be put into a new pile to the right of the others. *The object of the game is to finish with as few piles as possible.* (Aldous & Diaconis, 1999, p. 413)

Suppose our deck has 5 cards, numbered 1–5, and that they are shuffled so that they are ordered as 5 3 1 4 2. During the game, the piles might evolve as follows:

	1	1	1
3	3	3	3 2
5	5	5	5 4

and at the end of the game, we have two piles. Another (non-optimal) possibility is

		4	4 2
5	5 3	5 3 1	5 3 1

and we wind up with 3 piles. There is a simple algorithm (referred to as the "greedy algorithm") which always yields the minimum number of piles (see Aldous & Diaconis, 1999). The connection between the "solitaire" game described above and longest increasing subsequences is this: for any given shuffle, the minimum number of piles is exactly the longest increasing subsequence of the shuffle (when the shuffle is viewed as a permutation).

Over the past 40 years, mathematicians have studied the statistical behavior of the random variable $\ell_n(\sigma)$ when n , the size of the permutations, tends to infinity. Let $\mathbb{E}(\ell_n)$ denote the mean (or average) value of $\ell_n(\sigma)$, and let $\text{Var}(\ell_n)$ denote its variance, $\text{Var}(\ell_n) = \mathbb{E}(\ell_n^2) - (\mathbb{E}(\ell_n))^2$. Some natural questions are: How does $\mathbb{E}(\ell_n)$ grow with n ? How fast does the variance grow? Is there a notion of a central

limit theorem, or is there a limiting distribution for ℓ_n that emerges when n tends to ∞ ? Here are some results, both old and new, which answer these questions, and also demonstrate a striking connection between combinatorial questions and random matrix theory.

Result 1 (Logan & Shepp, 1977, see also Diaconis, 1995, Vershik & Kerov, 1997):

$$\lim_{n \rightarrow \infty} \frac{1}{\sqrt{n}} \mathbb{E}(\ell_n) = 2, \quad (3)$$

$$\lim_{n \rightarrow \infty} \frac{1}{\sqrt{n}} \text{Var}(\ell_n) = 2. \quad (4)$$

Result 2 (Baik et al., 1999):

$$\lim_{n \rightarrow \infty} \text{Prob} \left[\frac{\ell_n(\sigma) - 2n^{1/2}}{n^{1/6}} < x \right] = F(x), \quad (5)$$

where F is the Tracy–Widom distribution function (2). Result 2 was established in 1999. One remarkable aspect of this result is that it provides a mathematically precise connection between random permutations and random matrix theory (and Painlevé equations). There are now several proofs of this result as well as generalizations (see, e.g., Borodin et al. (2002)), and each proof contains different interconnections between areas of mathematics.

Further Developments

There have been a number of recent results that connect combinatorics to random matrix theory. Interesting generalizations of longest increasing subsequence problems have appeared. For example, Baik & Rains (2001) considered only those permutations that are their own inverses (also called involutions) and established results analogous to those mentioned above. Further generalizations to the study of "random words" have appeared (Tracy & Widom, 2001).

The Tracy–Widom distribution F has appeared in a variety of other contexts as well. For example, in the study of random domino tilings of the so-called Aztec diamond, the same distribution function appears in a natural scaling limit (Johansson, 2001). There is a notion of a "frozen region" of a domino tiling, and the boundary of this frozen region may be interpreted as a random variable, which is described, asymptotically, by the Tracy–Widom distribution function. This phenomenon is somewhat universal within random tiling problems as well—it has recently been established (Baik et al., 2004) that the same behavior appears in random rhombi tilings of hexagonal domains.

RANDOM MATRIX THEORY IV: ANALYTIC METHODS

In this article, we address various analytical issues that arise in random matrix theory (RMT) using techniques from the theory of Riemann–Hilbert problems (RHPs). We refer the reader to the previous three entries for more information on the physical applications and various algebraic developments in RMT, and to the entry on Riemann–Hilbert problem for more information on RHPs. The classic text on RMT is Mehta (1991); see also Deift (2000) for a pedagogic presentation of some recent analytical results.

We discuss only the so-called unitary ensembles (UEs), that is, ensembles of $N \times N$ Hermitian matrices $M = M^* = (M_{jk} = M_{jk}^R + iM_{jk}^I)$ with probability distributions

$$\begin{aligned} P_N(M) dM &= \frac{1}{Z_N} e^{-\text{tr } V(M)} dM \\ &= \frac{1}{Z_N} e^{-\text{tr } V(M)} \prod_{j=1}^N dM_{jj} \prod_{j < k} dM_{jk}^R \prod_{j < k} dM_{jk}^I, \end{aligned} \quad (1)$$

where $V : \mathbb{B} \rightarrow \mathbb{R}$ grows sufficiently rapidly at ∞ and Z_N is a normalization constant. The name UE refers to the fact that the distribution is invariant under unitary conjugation $M \rightarrow \tilde{M} = U M U^*$, with U unitary, that is, $P(\tilde{M}) d\tilde{M} = P(M) dM$. For information on other distributions such as orthogonal ensembles, see Tracy & Widom (1996, 1998) for some additional analytical developments. The special case in which $V(x) = x^2$ is called the Gaussian unitary ensemble (GUE), with $P_N(M) dM = \frac{1}{Z_N} e^{-\text{tr } M^2} dM$.

Under (1) the eigenvalues $\lambda_1(M) \geq \lambda_2(M) \geq \dots \geq \lambda_N(M)$ of a matrix M in the ensemble become random variables with distribution given by the Weyl integration formula (see Mehta, 1991)

$$P_N(\lambda) d^N \lambda = \frac{1}{Z'_N} e^{-\sum_i V(\lambda_i)} \prod_{i < j} (\lambda_i - \lambda_j)^2 \chi d^N \lambda, \quad (2)$$

where χ denotes the indicator function on $\mathbb{R}^N$ for the set $\lambda_1 \geq \dots \geq \lambda_N$. A statistic of basic importance is the gap probability

$$P_N(\theta; E) = \text{Prob} \{ M \text{ has no eigenvalues in } (E - \theta, E + \theta) \} \quad (3)$$

for $E \in \mathbb{R}$, $\theta > 0$. Scaling the eigenvalues in the standard way around the energy E , $\lambda \mapsto \lambda' = \gamma_N(\lambda - E)$, so that the expected number of eigenvalues per unit λ' -interval is 1, one considers the limit

$$P(y; E) = \lim_{N \rightarrow \infty} P_N(y/\gamma_N; E). \quad (4)$$

In the case of GUE, a calculation of Gaudin and Mehta (Mehta, 1991) using classical estimates showed that

$$\gamma_N \sim N^{1/2} \quad (5)$$

and that

$$P(y; E = 0) = \det(1 - S_y), \quad (6)$$

where S_y denotes the trace class operator with kernel

$$S_y(\xi, \eta) = \frac{\sin \pi(\xi - \eta)}{\pi(\xi - \eta)} \quad (7)$$

acting on $L^2(-y, y)$, the space of square integrable functions on the interval $(-y, y)$. The *universality conjecture* for the gap probability is the claim that under the correct scaling, (6) is true with the same right-hand side for all suitable V and E . The only thing that depends on V is the scaling parameter γ_N . Universality conjectures for other statistical quantities are discussed briefly below.

In this article we present a sketch of how to prove the universality conjecture for (6) following Deift et al. (1999a,b) in which the authors consider two kinds of potentials V

- (i) $V(x) = t_{2m} x^{2m} + \dots + t_0$, $t_{2m} > 0$,
- (ii) $V(x) = N Q(x)$, where

- (a) $Q(x)$ is real analytic in a neighborhood of $\mathbb{R}$
- (b) $|Q(x)|/|\log x| \rightarrow +\infty$ as $|x| \rightarrow \infty$.

In order to prove (6), one must choose E in the support of the so-called equilibrium measure for V (see Step 4 Analytical considerations (ii) below).

The universality conjecture was first considered in the physics literature in Brézin & Zee (1993), in the mathematical literature in Pastur and Scherbina (1997), and in the special case $V(x) = x^4 + tx^2$, $t < 0$, in Bleher & Its (1999). The method in Bleher & Its has common elements with Deift et al. (1999a,b), but in addition Bleher & Its uses certain isomonodromy ideas.

Step 1: Representation in terms of orthogonal polynomials

Using an earlier calculation of Gaudin and (2), Gaudin and Mehta (Mehta, 1991) showed that

$$P_N(\theta, E = 0) = \det(1 - K_N), \quad (8)$$

where K_N is the finite rank operator acting on $L^2(E - \theta, E + \theta)$ with kernel

$$K_N(x, y) = \sum_{j=0}^{N-1} \phi_j(x) \phi_j(y), \quad (9)$$

where $\phi_j(x) = e^{-(1/2)V(x)} p_j(x)$ and $p_j(x) = k_j x^j + \dots$, $k_j > 0$, $j \geq 0$, are the orthonormal polynomials generated by the measure $e^{-V(x)} dx$,

$$\int_{\mathbb{R}} p_j(x) p_l(x) e^{-V(x)} dx = \delta_{jl}. \quad (10)$$

By the Christoffel–Darboux formula (Szegő, 1975), K_N can be expressed in terms of p_N and p_{N-1} and so the proof of (6) reduces to the evaluation of the asymptotics (so-called *Plancherel–Rotach* asymptotics) for $p_N(E + x/\gamma_N)$, $p_{N-1}(E + x/\gamma_N)$ as $N \rightarrow \infty$, for polynomials orthonormal with respect to a weight as in (10). For GUE, the p_N 's are Hermite polynomials and such asymptotics can be found in the classical literature (Plancherel & Rotach, 1929). This is why Gaudin and Mehta were able to derive (6) for GUE, but for general weights $e^{-V(x)} dx$ the derivation of Plancherel–Rotach asymptotics is crucial.

Step 2: Introduction of Riemann–Hilbert Problem (RHP)

Write $p_j(x) = k_j \pi_j(x)$, so $\pi_j(x) = x^j + \dots$. Following Fokas et al. (1991), the orthonormal polynomials p_j can be recovered by solving an RHP. Let the z -plane contour $\Sigma = \mathbb{R}$ be oriented from left to right so that the $(+)$ side (respectively, $(-)$ side) lies to the left (respectively, right) as one traverses Σ in the direction of

the orientation. Define the jump matrix

$$v(z) = \begin{pmatrix} 1 & e^{-V(z)} \\ 0 & 1 \end{pmatrix} \text{ for } z \in \Sigma,$$

and for any nonnegative integer q , let $Y = Y^{(q)} = (Y_{ij})_{1 \leq i, j \leq 2}$ be the (unique) 2×2 solution of the RHP (Σ, v) .

- (i) $Y(z)$ is analytic in $\mathbb{C} \setminus \Sigma$,
- (ii) $Y_+(z) = Y_-(z)v(z)$, $z \in \mathbb{R}$, where $Y_{\pm}$ denotes the plus/minus boundary values of $Y(z)$, normalized so that
- (iii) $Y(z) \begin{pmatrix} z^{-q} & 0 \\ 0 & z^q \end{pmatrix} \rightarrow \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$ as $z \rightarrow \infty$.

Then

$$\pi_q(z) = Y_{11}(z), \quad \pi_{q-1}(z) = -Y_{21}(z)/2\pi i k_{q-1}^2 \quad (11)$$

and

$$k_q = \sqrt{-(Y_{21})_1/2\pi i}, \quad (12)$$

where $Y_{21}(z) = (Y_{21})_1 z^{q-1} \dots$.

Thus, the evaluation of Plancherel–Rotach asymptotics for p_q , p_{q-1} reduces to the asymptotics of the RHP (Σ, v) as $q = N \rightarrow \infty$.

Step 3: Steepest-descent method applied to the RHP

We use the steepest-descent method for the RHPs introduced in Deift & Zhou (1993) and extended in Deift et al. (1997) to include fully nonlinear oscillations (See **Riemann–Hilbert problem**). We consider the case where $V(x) = N Q(x)$ with properties (a) and (b) on the left above and as in Deift et al. (1999a). The case where $V(x) = t_{2m} x^{2m} + \dots + t_0$ can be reduced to this case with lower-order errors by scaling (see Deift et al., 1999b).

Suppose there exists a union of $n+1$ disjoint intervals $J = \cup_{i=0}^n (b_i, a_i + 1)$ in $\mathbb{R}$, $b_0 < a_1 < \dots < b_n < a_{n+1}$, a real number l , and a function $g(z)$ with the following properties:

$$g(z) \text{ is analytic in } \mathbb{C} \setminus \bar{J}, \quad (13)$$

$$g(z) = \log z + o(1) \text{ as } z \rightarrow \infty, \quad (14)$$

$$g_+(z) + g_-(z) - V(z) - l \leq 0 \text{ for } z \in \mathbb{R} \setminus \bar{J}, \quad (15)$$

where $\bar{J}$ denotes the closure of J , and where equality holds for at most a finite number of points,

$$g_+(z) - g_-(z) \in i\mathbb{R}, \quad (16)$$

for all real z and is constant in each component of $\mathbb{R} \setminus \bar{J}$,

$$g_+(z) + g_-(z) - V(z) - l = 0 \text{ for } z \in \bar{J}, \quad (17)$$

$$i(g'_+ - g'_-) \geq 0 \text{ for } z \in J, \quad (18)$$

where equality holds for at most a finite number of points. As before, $g_\pm$ denotes the boundary values of $g(z)$.

Now define

$$M(z) \equiv e^{-Nl/2\sigma_3} Y(z) e^{-(g(z)-l/2)\sigma_3},$$

$$\sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \quad (19)$$

A simple calculation using (13) and (14) shows that $M(z)$ solves a RHP normalized at infinity.

- (i) $M(z)$ is analytic in $\mathbb{C} \setminus \mathbb{R}$
- (ii) $M_+(z) = M_-(z)v_M(z)$, where $v_M(z) =$

$$\begin{pmatrix} e^{-N(g_+(z)-g_-(z))} & e^{N(g_+(z)+g_-(z)-V(z)-l)} \\ 0 & e^{N(g_+(z)-g_-(z))} \end{pmatrix},$$

$$z \in \mathbb{R},$$

- (iii) $M(z) \rightarrow I$ as $z \rightarrow \infty$.

As we now show, the properties of $g(z)$ are chosen carefully so that the jump matrix v_M takes a specific form. By (17)

$$v_M(z) = \begin{pmatrix} e^{-N(g_+(z)-g_-(z))} & 1 \\ 0 & e^{N(g_+(z)-g_-(z))} \end{pmatrix},$$

$$z \in J, \quad (20)$$

and by (16)

$$v_M(z) = \begin{pmatrix} e^{-iN\Omega_j} & e^{N(g_+(z)+g_-(z)-V(z)-l)} \\ 0 & e^{iN\Omega_j} \end{pmatrix},$$

$$z \in (a_j, b_j), \quad j = 1, \dots, n, \quad (21)$$

for some real constants Ω_j . Furthermore, if the inequality in (15) is strict then

$$v_M(z) = \begin{pmatrix} e^{-iN\Omega_j} & o(1) \\ 0 & e^{iN\Omega_j} \end{pmatrix}, \quad z \in (a_j, b_j)$$

as $N \rightarrow \infty$. (22)

By (17), for $z \in J$,

$$G \equiv g_+ - g_- = 2g_+ - V(z) - l = -2g_- + V(z) + l$$

and so has an analytic continuation to a suitable neighborhood U of J . If the inequality in (18) is strict, it follows by the Cauchy-Riemann conditions (make U smaller if necessary) that $\operatorname{Re} G(z) \geq 0$ for $z \in \{\operatorname{Im} z \geq 0\} \cap U$, respectively. Extend $\Sigma = \mathbb{R}$ to a new contour $\tilde{\Sigma}$ consisting of $\mathbb{R}$ together with the boundary of $n+1$ lens-shaped regions, one region surrounding each interval (b_{j-1}, a_j) in J , as indicated in Figure 1.

Figure 1. The Riemann-Hilbert problem $(\tilde{\Sigma}, \tilde{v})$.

Note the factorization for v_M on J

$$\begin{pmatrix} e^{-NG} & 1 \\ 0 & e^{NG} \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ e^{NG} & 1 \end{pmatrix} \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$$

$$\begin{pmatrix} 1 & 0 \\ e^{-NG} & 1 \end{pmatrix} \equiv v_- v_+ v_-. \quad (23)$$

The final algebraic step in the procedure is to define

- (i) $\tilde{M}(z) \equiv M(z)$ outside the lens-shaped regions,
- (ii) $\tilde{M}(z) \equiv M(z) \begin{pmatrix} 1 & 0 \\ -e^{-NG} & 1 \end{pmatrix}$ in the upper lens regions,
- (iii) $\tilde{M}(z) \equiv M(z) \begin{pmatrix} 1 & 0 \\ e^{NG} & 1 \end{pmatrix}$ in the lower lens regions.

Then $\tilde{M}$ solves the normalized RHP $(\tilde{\Sigma}, \tilde{v})$

- (i) $\tilde{M}(z)$ is analytic in $\mathbb{C} \setminus \tilde{\Sigma}$,
- (ii) $\tilde{M}_+(z) = \tilde{M}_-(z)\tilde{v}(z)$, $z \in \tilde{\Sigma}$,
- (iii) $\tilde{M}(z) \rightarrow I$ as $z \rightarrow \infty$,

where

- (i) $\tilde{v}(z) = v_M(z)$ for $z \in \mathbb{R} \setminus \bar{J}$,
- (ii) $\tilde{v}(z) = v_\pm(z)$ for $z \in \tilde{\Sigma} \cap \mathbb{C}_\pm$,
- (iii) $\tilde{v}(z) = v_0(z)$ for $z \in J$

as indicated in Figure 1.

Now the situation is clear. The above computations show that as $N \rightarrow \infty$, $\tilde{v}(z) \rightarrow v^\infty(z)$, where

- (i) $v^\infty(z) = \begin{pmatrix} e^{-iN\Omega_j} & 0 \\ 0 & e^{iN\Omega_j} \end{pmatrix}$ for $z \in (a_j, b_j)$,
 $j = 1, \dots, n$,
- (ii) $v^\infty(z) = I$ for $z \in (-\infty, b_0) \cup (a_0, \infty)$,
- (iii) $v^\infty(z) = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$ for $z \in J$,
- (iv) $v^\infty(z) = I$ for z on the boundary of any of the lens-shaped regions.

Thus, we expect that as $N \rightarrow \infty$, $\tilde{M}(z) \rightarrow M^\infty(z)$, where $M^\infty(z)$ solves the RHP $(\tilde{\Sigma}, v^\infty)$

- (i) $M^\infty(z)$ is analytic in $\mathbb{C} \setminus \tilde{\Sigma}$,
- (ii) $M_+^\infty(z) = M_-^\infty(z)v^\infty(z)$, $z \in \tilde{\Sigma}$,
- (iii) $M^\infty(z) \rightarrow I$ as $z \rightarrow \infty$.

It turns out that the RHP $(\tilde{\Sigma}, v^\infty)$ can be solved explicitly in terms of theta functions (Deift et al., 1999a), thus yielding asymptotic formulae for $p_N(E+x/\gamma_N)$, $p_{N-1}(E+x/\gamma_N)$ as $N \rightarrow \infty$, which then leads to the proof of the universality conjecture (6) as indicated above.

Step 4: Analytical considerations

In order to make the above schema rigorous, many analytical difficulties must be addressed:

- (i) One must show that J , l , and $g(z)$ with properties (13)–(18) actually exist. This can be done by considering the minimization problem

$$E_V = \inf_{\mu \in \mathcal{M}} \left(\int \int \log |s - t|^{-1} d\mu(s) d\mu(t) + \int V(t) d\mu(t) \right), \quad (24)$$

where $\mathcal{M}$ is the space of probability measure on $\mathbb{R}$. It turns out (Saff & Totik, 1997) that the infimum is achieved at a unique measure $\mu = \mu_V$, the so-called *equilibrium measure* for V . For $V = NQ$ satisfying (i) and (ii) above, a result of Deift, Kriecherbauer and McLaughlin shows that $d\mu_V(s) = \psi_V(s) ds$ is absolutely continuous with respect to Lebesgue measure and is supported on a finite union of intervals J_V . Then quite remarkably

$$g(z) \equiv \int_{\mathbb{R}} \log(z - s) d\mu_V(s) \quad (25)$$

has the desired properties (13)–(18) on $J = J_V$, provided l is chosen to be the Lagrange multiplier associated with the constraint $\int d\mu = 1$ in the minimization problem E_V .

- (ii) The scaling parameter γ_N must be determined. In order to obtain the universality limit (6) one must consider only points E in the support of μ_V , $\psi_V(E) > 0$. For such E , one takes $\gamma_N \equiv N\psi_V(E)$. If $\psi_V(E) = 0$, the limit in (4) (if it exists!) is *different* from (6). In this connection, see (26) below.
- (iii) The convergence of $\tilde{v}(z)$ to $v^\infty(z)$ is not uniform on $\tilde{\Sigma}$ as $N \rightarrow \infty$, leading in particular to difficulties at the end points of J .
- (iv) The inequalities in (15) and (18) may not be strict.

The analytical heart of the problem lies in addressing the latter three points, and we refer the reader to Deift et al. (1999a) for further details.

The asymptotic behavior of $P(y, E=0) = \det(1 - S_y)$ as $y \rightarrow \infty$ can itself be evaluated using Riemann–Hilbert techniques (see Deift et al., 1997). The work in Deift et al. (1997) follows on the earlier work of Widom (1994, 1995), who uses more classical techniques. The paper by Deift et al. (1997) is the first application of RHP techniques to random matrix theory.

Universality conjectures for other statistical quantities, such as the k -point correlation function and the nearest-neighbor spacing distribution, can also be proved using the above methods (see Deift et al., 1999a; Deift, 2000). For GUE, Tracy & Widom (1994) proved the beautiful result that if $\lambda_1(M)$ is the largest

eigenvalue of a GUE matrix M , then

$$\lim_{N \rightarrow \infty} \text{Prob}((\lambda_1(M) - \sqrt{2N})2^{1/2}N^{1/6} \leq t) = F(t), \quad (26)$$

where $F(t)$ is the so-called *Tracy–Widom distribution*

$$F(t) = e^{-\int_t^\infty (s-t)u^2(s) ds},$$

where $u(s)$ is the unique solution (Hastings & McLeod, 1980) of the Painlevé II equation $u'' = 2u^3 + su$ with asymptotics $u(s) \sim \text{Ai}(s)$ as $s \rightarrow \infty$. Here $\text{Ai}(s)$ is the classical Airy function. As long as $\psi_V(s)$ behaves “generically” near the right end point of J , $\psi_V(s) \sim \sqrt{s - a_{N+1}}$, $s \sim a_{N+1}$, one can use the methods of Deift et al. (1999a) to show that the behavior of $\lambda_1(M)$ is also universal as $N \rightarrow \infty$; that is, once the correct scaling parameters at a_{N+1} are inserted, the same limit (26) is true for all UEs. As noted in the entry on Riemann–Hilbert problem, the distribution $F(t)$ arises, in particular, in the solution of Ulam’s problem in Baik et al. (1999).

RANDOM PROCESSES

See **Stochastic processes**

RANDOM WALKS

As conceptually simple stochastic processes, random walks have a plethora of practical modeling applications, leading to elegant and sometimes counter-intuitive mathematics. Consider a particle constrained to move in one dimension, moving one unit to the left or right at each unit time step, and with the direction of motion for each time step chosen at random and independently of the particle's position or history. If the particle's position after n time steps is $S(n)$, one can assert

$$S(n) = S(0) + \sum_{i=1}^n X_i, \quad (1)$$

where each X_i is an independent identically distributed (IID) random variable taking values $+1$ with probability (say) p and -1 with probability $1-p$. If $p = 1-p = \frac{1}{2}$, then the simple random walk (SRW) has no “preferred direction” and is unbiased. If $p > \frac{1}{2}$, then the particle is more likely to move right than left at

each time step; the SRW is biased. The traditional pedagogical example imagines a drunken student's erratic progress along a street, where bias might be caused by the street being inclined or having a pub at one end.

Basic Results

The statistics of Equation (1) are simple and intuitively reasonable; thus

$$\begin{aligned} E(S(n)) &= S(0) + n(2p - 1) \\ \text{Var}(S(n)) &= 4np(1 - p), \end{aligned} \quad (2)$$

so the SRW moves with an average speed of $2p - 1$ and spreads about the mean as $\sqrt{n}$ (characteristic of diffusive processes). This spread is greatest when the SRW is unbiased.

One can readily prove that the SRW is temporally and spatially homogeneous and Markovian (i.e., it does not matter where one places the origin of time or space, and conditional on the present, the future is independent of the past). Assuming without loss of generality $S(0) = 0$,

$$\begin{aligned} P(S(n) = a) &= C_{(n+a)/2}^n p^{(1/2)(n+a)} \\ &\quad \times (1 - p)^{(n-a)/2}, \end{aligned} \quad (3)$$

the particle moves $(n + a)/2$ steps right and $(n - a)/2$ steps left to give a total of n steps and a net right displacement of a , and there are $C_{(n+a)/2}^n$ equally likely paths achieving this. N.B. for a to be attainable in n steps one requires $|a| \leq n$ and $(n + a)/2$ to be an integer i.e., only odd positions are attainable at odd times, hence, the mysterious factor of 2 in Equation (5).

Results exploiting symmetries, homogeneities, and combinatorics, and also applications of probability- and moment-generating functions, are summarized in Grimmett & Stirzaker (2001, Chapters 3 and 4). More interesting questions involving absorption or reflection at barriers, dealt with using linear difference equations; where the nature of the barriers, dictates the appropriate boundary conditions, are also addressed therein.

Continuous Limit: Diffusion

For an unbiased SRW, manipulation of Equation (3) reveals, for sufficiently large a and n ,

$$P(S(n) = a) \approx \sqrt{\frac{2}{\pi n}} \exp\left(\frac{-a^2}{2n}\right), \quad (4)$$

resembling a normal (Gaussian) probability distribution (Murray, 2002, Chapter 9). Indeed, if one lets the discrete space and time steps have sizes Δx and Δt , respectively, and forces these to zero such that

$$\lim_{\Delta x \rightarrow 0, \Delta t \rightarrow 0} \frac{(\Delta x)^2}{2\Delta t} = D \quad (5)$$

for some finite constant D (the diffusion coefficient), then one arrives at a diffusion equation,

$$\frac{\partial P}{\partial t} = D \frac{\partial^2 P}{\partial x^2}, \quad (6)$$

where $P(x, t)$ is the probability density function for the particle's position x at time t . Solutions of Equation (6) take the form indicated by Equation (4):

$$P(x, t) = \frac{1}{\sqrt{4\pi Dt}} \exp\left(-\frac{x^2}{4Dt}\right). \quad (7)$$

An alternative derivation, using Taylor series expansions of $P(x, t)$ (Murray, 2002, Chapter 9), lacks beauty and elegance but is more readily generalizable to the nonlinear RWs discussed below (Othmer & Stevens, 1997). If the SRW is biased, then an advection term,

$$v \frac{\partial P}{\partial x}$$

(where v represents the average velocity in the preferred direction) is added to the left-hand side of (6). If one considers $P(x, t)$ to represent a density of particles (rather than a probability density for a single particle), then one can incorporate local dynamics (e.g., chemical reactions or biological reproduction) at each point; a reaction term

$$f(P, x, t)$$

appears on the right-hand side of (6). The description of SRWs using diffusion (or more generally reaction-diffusion-advection) equations allows standard partial differential equation methods to be applied, often elucidating information concerning wave-like and spatially structured solutions (Murray, 2002; Okubo & Levin, 2001).

The extension of the SRW into higher dimensions presents no great conceptual, nor mathematical, challenges. If the processes governing steps in orthogonal directions are mutually independent, then one applies the preceding results to each direction separately. More realistically, suppose that at each time step a unit distance is moved in a direction chosen randomly from the infinite number of possibilities. Again, one can show that the process is, on average, diffusive (Denny & Gaines, 2000, Chapter 6):

$$E(S(n)) = S(0) \text{ and } \text{Var}(S(n)) = n. \quad (8)$$

Importantly, motion in more than one spatial dimension allows more realistic random walk models to be developed, some of which are mentioned below.

Random Walks in Biology

Random walks have been widely applied in the life sciences. While ostensibly describing a particle's position, the modeled quantity might equally well refer to the amount of food consumed by an animal, the

frequency of an allele in a population, or the contentious notion of "fitness." Crucially, random walk models are developed using local rules of "motion" at the level of the "individual" (organism/cell/molecule, etc.) before any scaling-up to a population level description is undertaken. This encourages the modeller to adhere to realistic assumptions and provides a link between concrete experimental observation and theory.

Several accessible applications are presented in Denny & Gaines (2000, Chapters 5 and 6). For example, Equation (6) can be solved to indicate the rate at which nutrients reach an idealized organism, D being strongly dependent on the organism's environment. Such considerations help to explain relative sizes of aquatic and aerial organisms and underly the varying mechanisms of nutrient transport in plant root systems. More complicated applications deal with the distribution of receptors on cell walls, the random drift to fixation of alleles in finite populations, and the energetics of protein folding. For more mathematically demanding applications involving spatial patterns and reaction-diffusion equations, see Murray (2002) and Okubo & Levin (2001).

Nonlinear Random Walks

The basic concept of a particle "deciding" (using IID random variables) its next direction at every step may be excessively restrictive, particularly in biology. For example, a particle moving in two dimensions may be likely to choose a direction similar to that used during the previous time step or may have some fixed preferred direction toward which its trajectory is biased. The mathematics of such "correlated" RWs is discussed in Othmer et al. (1988).

Alternatively, motion may be influenced by interactions with the local environment (reinforced RWs) leading to nonlinear generalizations of the simple diffusion equation; under reasonable assumptions, Equation (6) may be more properly expressed

$$\frac{\partial P}{\partial t} = D \frac{\partial}{\partial x} \left(\frac{\partial}{\partial x} \left[\ln \frac{P}{\tau(W)} \right] \right), \quad (9)$$

where $\tau(W)$ represents a transition rate dictated by the environment W . Such systems can exhibit properties not found in diffusive SRW formulations; particles may tend to aggregate rather than disperse and may reach locally infinite or zero densities in finite time (Othmer & Stevens, 1997).

Numerical simulation of such systems can be built up from individual-level rules as in Sleeman & Wallis (2002) and Figure 1, where the authors model angiogenesis (the movement of endothelial cells to create a blood supply to an avascular tumor). The cells' motions are dictated by chemical gradients between the tumor and the blood vessel: at first the attractive signal from the tumor is weak and the motion tortuous, but

Figure 1. Tumor angiogenesis modeled as a reinforced random walk. (Used with kind permission of I.P. Wallis and B.D. Sleeman, Department of Mathematics, University of Leeds, U.K.)

once the tumor's signal is sufficiently strong a more directed motion is observed.

RATCHETS

An essential and striking feature of living cells is their ability to generate mechanical motion and forces. Important examples are cell motility, muscle contraction, and active mass transport within cells, among other active phenomena in biology. These motions and forces are generated at the molecular level by protein molecules (called molecular motors

or pumps) that are driven by chemical reactions in situations far from equilibrium (Astumian, 1997; Jülicher et al., 1997).

Two types of molecular motors are classified as linear (or translational) and rotary (or rotatory). Within the first class, motor proteins are classified into several families: myosins, kinesins, and dyneins. Each of these interacts specifically with a certain type of filament along which it is able to move in the presence of adenosine triphosphate (ATP), which is a chemical fuel. The filaments serve as guides or tracks for the motor motion. Two types of filaments play this role: microtubules and actin filaments. Both are formed by a polymerization process from identical monomers (actin and tubulin monomers, respectively), resulting in a regular and periodic one-dimensional structure. An important feature is their polarity; thus the asymmetry of the monomers that form a polar filament structure is essential for motor operation as it defines the direction of motion.

A typical representative of rotary molecular motors is ATP synthase composed of two coupled rotary engines: a membrane-embedded unit F_0 and a water-surrounded part F_1 (Oster & Wang, 2000) ATP synthase works as a reversible motor-pump machine. Thus, the proton flow through F_0 is believed to generate a mechanical torque driving the F_1 motor to synthesize ATP, and using the hydrolysis energy of ATP, the F_1 motor can drive the F_0 motor in reverse to pump protons. Direct observation of the rotation of the F_1 motor has been demonstrated in fascinating experiments by Japanese scientists (Noji et al., 1997).

Thus, molecular motors are microscopic objects that unidirectionally move along one-dimensional periodic structures. Because the motor operation is considered on the molecular level, the motor must be a Brownian object, subject to random fluctuations. A conversion (rectification) of random fluctuations $F(t)$ into useful work (i.e., a directed motion) is called a "ratchet effect." (The names *thermal ratchet*, *Brownian motor*, *Brownian rectifier*, *mechanical diode*, *stochastic ratchet*, or simply *ratchet* are also in use.) A comprehensive review of the work on ratchets and their practical applications is available in Reimann (2002).

Historically, the problem of converting Brownian motion (in general, unbiased random fluctuations) into useful work and its consistency with the second law of thermodynamics was introduced in a conference talk by Marian Smoluchowski in 1912 (Smoluchowski, 1912) and later popularized and extended by Richard Feynman (Feynman et al., 1963), using a so-called "ratchet and pawl" gadget. A simple stochastic model of this rectifying process (called a Smoluchowski–Feynman's ratchet) can be described using the overdamped Langevin equation for a Brownian particle moving in a one-dimensional viscous medium with

friction coefficient η in the presence of a constant force F :

$$\eta\dot{x}(t) = -V'(x(t)) + F + \xi(t). \quad (1)$$

Here, the overdot and the prime denote differentiation with respect to the time t and the particle coordinate x , respectively. The potential $V(x)$ is a periodic function with period L , $V(x+L) = V(x)$, which has a broken parity symmetry. More precisely, this breaking of symmetry means that there is no Δx such that $V(-x) = V(x + \Delta x)$ for all x . A typical example of such a ratchet potential is a piecewise-linear (saw-tooth) function, consisting of two continuously matched linear pieces per period L , one with negative and one with positive slope, one being steeper than the other. The stochastic force $\xi(t)$ is a Gaussian white noise of zero mean, $\langle \xi(t) \rangle = 0$, satisfying the fluctuation-dissipation relation (Risken, 1989)

$$\langle \xi(t)\xi(s) \rangle = 2\eta k_B T \delta(t-s), \quad (2)$$

where k_B is Boltzmann's constant, $2\eta k_B T$ is the noise intensity or strength (T is absolute temperature), and $\delta(t)$ is Dirac's delta function.

The probability densities induced by the above equations obey a Fokker-Planck (FP) equation, which can be written in the form of a conservation law for probability, namely, a continuity equation (Risken, 1989)

$$\partial_t P(x, t) + \partial_x J(x, t) = 0. \quad (3)$$

Here the probability density $P(x, t)$ satisfies the normalization condition

$$\int_{-\infty}^{\infty} P(x, t) dx = 1, \quad (4)$$

whereas the probability current is defined by

$$J(x, t) \doteq -\eta^{-1}[U'(x) + k_B T \partial_x]P(x, t), \quad (5)$$

with the ratchet potential $V(x)$ and the force F being incorporated into a single effective potential

$$U(x) \doteq V(x) - Fx. \quad (6)$$

The quantity of foremost interest in the context of transport in periodic systems is the particle current, defined as the time-dependent ensemble average over the velocities, $\langle \dot{x}(t) \rangle$ (where for convenience the argument t is omitted). From this definition, the general connection between the probability current and the particle current is obtained as

$$\langle \dot{x} \rangle = \int_{-\infty}^{\infty} J(x, t) dx. \quad (7)$$

Instead of solving the FP equation (3) describing the particle transport in periodic systems but with zero boundary conditions at infinity, it is convenient to rewrite it in terms of reduced probabilities

(Reimann, 2002):

$$\begin{aligned} \hat{P}(x, t) &\doteq \sum_{n=-\infty}^{\infty} P(x + nL, t), \quad \hat{J}(x, t) \\ &\doteq \sum_{n=-\infty}^{\infty} J(x + nL, t), \end{aligned} \quad (8)$$

which are evidently periodic functions with period L . Furthermore, Equations (4) and (7) are transformed to

$$\int_0^L \hat{P}(x, t) dx = 1 \quad (9)$$

and

$$\langle \dot{x} \rangle = \int_0^L \hat{J}(x, t) dx, \quad (10)$$

respectively. Indeed, because $V(x)$ is periodic with period L , with $P(x, t)$ being a solution of the FP equation (3), $\hat{P}(x + nL, t)$ is also a solution for any integer n . Next, since the FP equation is linear, Equations (3) and (5) are also satisfied by the reduced quantities (8). Therefore, it is sufficient to solve an FP equation with periodic boundary conditions.

If the reduced dynamics assumes a steady state $\hat{P}^{\text{st}}(x)$ in Equation (3), then the reduced probability current $\hat{J}(x, t) = \hat{J}^{\text{st}}$ becomes independent of x and t . Multiplying this equation by x and integrating both its sides from x to $x + L$, one finds that the particle current takes the form

$$\langle \dot{x} \rangle = L \hat{J}^{\text{st}}, \quad (11)$$

as expected. Moreover, using Equations (3), (5), and (11), it can easily be checked that the steady-state solution is given by (Stratonovich, 1969; Reimann, 2002)

$$\hat{P}^{\text{st}}(x) = \mathcal{N} \frac{\eta}{k_B T} e^{-U(x)/k_B T} \int_x^{x+L} e^{U(y)/k_B T} dy, \quad (12)$$

$$\langle \dot{x} \rangle = L \mathcal{N} \left[1 - e^{[U(L) - U(0)]/k_B T} \right], \quad (13)$$

$$\mathcal{N} \doteq \frac{k_B T}{\eta} \left[\int_0^L dx \int_x^{x+L} e^{[U(y) - U(x)]/k_B T} dy \right]^{-1}. \quad (14)$$

This solution is valid for a general potential $U(x)$ provided $U'(x+L) = U'(x)$. For the specific form (6), $U(L) - U(0) = -LF$, and therefore, as expected, the sign of the particle current (13) coincides with the sign of F . The absence of an average particle current ($\langle \dot{x} \rangle = 0$) if $F = 0$, in spite of the broken spatial symmetry, agrees with the second law of thermodynamics, like in the original ratchet and pawl gadget (Feynman et al., 1963). However, if the force

F in Equation (1) depends on time, a rectified motion (ratchet effect) may occur in an asymmetric system.

For the occurrence of the ratchet effect, it is sufficient to show that $\langle \dot{x} \rangle \neq 0$ provided $\langle F(t) \rangle = 0$. If the changes of $F(t)$ are extremely slow, then at any given instant t , the particle current has practically the same value as the steady-state current (13) with a static tilt F . In this adiabatic approximation, the time t plays the role of a parameter and using result (13) for a periodic driving force $F(t + \mathcal{T}) = F(t)$, one finds the time-averaged particle current:

$$\langle \dot{x} \rangle = \frac{1}{\mathcal{T}} \int_0^{\mathcal{T}} \frac{L k_B T [1 - e^{-L F(t)/k_B T}]}{\eta \int_0^L dx \int_x^{x+L} e^{[V(y) - V(x) - F(t)(y-x)]/k_B T} dy} dt. \quad (15)$$

For general analytical conclusions, the adiabatic expression (15) is still too complicated. Only in simple special cases may one predict the direction of the current. As an example, consider the case of when the tilting force $F(t)$ takes only two possible values $\pm F_0$ with very rare deterministic or random flips for which $\langle F(t) \rangle = 0$, and $V(x)$ is a piecewise linear potential with two continuously matched linear pieces per period L , the slopes of which are different (one steeper and one flatter). Outside this fundamental cell of length L , the potential is periodically continued. In this case, the integrals in Equation (15) can be calculated analytically, yielding an explicit expression (Magnasco, 1993), which is positive if the flatter slopes are arranged in the positive direction. Intuitively, this ratchet effect can be understood as follows. For F_0 within a certain range, one of the two tilted asymmetric potentials $V(x) \mp F_0 x$ does not exhibit any extrema and, therefore, supports a permanent downhill motion (even if $T = 0$), while the other still exhibits extrema acting as motion-blocking barriers. Below this window, both $V(x) \mp F_0 x$ exhibit barriers and, thus, prohibit deterministic motion. Because the barrier induced by the steeper slope of $V(x)$ is higher than that induced by the flatter slope, a weak thermal noise induces the current in the direction of the flatter slope.

Alternatively, the ratchet effect in a spatially periodic system can be achieved under a time-dependent variation (pulsation) of the potential shape without affecting its spatial periodicity. Therefore, Equation (1) can be generalized to include both a pulsating $f(t)$ and tilting $F(t)$ forcing as follows (Jülicher et al., 1997; Reimann, 2002):

$$\eta \dot{x}(t) = -V'[x(t), f(t)] + F(t) + \xi(t), \quad (16)$$

where $V'(x, f) \doteq \partial_x V(x, f)$. Here $F(t)$ may contain a load force or torque, generally depending on time t .

Thus, two fundamental classes of ratchet models arise from Equation (16). The first comprises models

with $F(t) \equiv 0$, which are called “pulsating” ratchets. Within these, the first main subclass, called “fluctuating potential” ratchets (Astumian & Bier, 1994; Prost et al., 1994), is obtained when $f(t)$ in Equation (16) is additive, i.e., $V(x, f(t)) = V(x)[1 + f(t)]$. This subclass contains as a special case the “on-off” ratchets (Ajdari & Prost, 1992) when $f(t)$ takes only two values, one of them being -1 (potential “off”). The on-off ratchets are suitable for experimental realizations and have been demonstrated (Rousselet et al., 1994) by means of colloidal polystyrene latex spheres suspended in solution and exposed to a dielectric ratchet potential, created by a series of “Christmas-tree” electrodes, which were turned on and off periodically. A similar experimental setup was used by Fauchaux & Libchaber (1995) but with solutions containing two different species of particles at a time. As a result, it was demonstrated that they can be separated. A further experimental verification of on-off ratchets has been performed (Fauchaux et al., 1995) using polystyrene spheres confined to an effective one-dimensional ratchet potential by laser-optical trapping techniques (optical tweezers). The second subclass of pulsating ratchets, called “traveling potential” ratchets, have potentials of the form $V(x, f(t)) = V(x - f(t))$.

The second class are models with $f(t) \equiv 0$, called “tilting” ratchets (Magnasco, 1993), so that $V(x, f(t)) = V(x)$ in Equation (16). When $V(x)$ is a ratchet potential, then $F(t)$ is mostly considered as a symmetric function. If $F(t)$ is a stochastic process, one speaks of a “fluctuating force” ratchet. The case of a tilting ratchet with a periodic driving $F(t)$ is of particular experimental relevance and carries the obvious name “rocking” ratchet.

Clearly, there are many possible combinations and generalizations of these classes; for example, a simultaneously pulsating and tilting ratchet or the simultaneous breaking of more than one symmetry (Reimann, 2002). For various applications in physics, chemistry, and biology, see Astumian (1997), Jülicher et al. (1997), and Reimann (2002).

RAYLEIGH AND RAMAN SCATTERING AND IR ABSORPTION

When an electromagnetic wave, $E = E_0 \cos 2\pi\nu t$, irradiates a molecule, a crystal, or a disordered substance, the energy may be scattered, absorbed, or transmitted. In the scattering process, the irradiated medium becomes polarized and the induced dipole moment (or electric polarization),

$$P = \alpha E + \dots = \alpha E_0 \cos 2\pi\nu t + \dots \quad (1)$$

oscillates synchronously with the electromagnetic field. The dipole radiates energy (the scattering), and α is the polarizability (usually a second-order tensor).

Irradiating with ultraviolet or visible light of frequency ν induces an electronic polarization that is modulated by the vibrational frequencies ($\nu_i, \nu_j, \nu_k, \dots$) of the substance. Assuming a simple diatomic molecule, vibrating with frequency ν_1 , the nuclear displacement is $q = q_0 \cos 2\pi\nu_1 t$, and $\alpha = \alpha_0 + (\partial\alpha/\partial q)_0 q$, then

$$P = \alpha_0 E_0 \cos 2\pi\nu t + \frac{1}{2} \left(\frac{\partial\alpha}{\partial q} \right)_0 q_0 E_0 [\cos[2\pi(\nu + \nu_1)t] + \cos[2\pi(\nu - \nu_1)t]] \quad (2)$$

The emitted intensity is proportional to the square of the polarization $I \approx P^2$.

Figure 1. Level schemes for electronic and vibrational transitions involved in Raman scattering, resonance Raman scattering, and infrared absorption.

Rayleigh scattering occurs if the energy, ν , of the scattered photon is equal to that of the incident one (first term of Equation (2)). Rayleigh (1871) demonstrated that the Earth's blue sky was due to scattering of light by atmospheric particles, with a scattering intensity proportional to the inverse fourth power of the wavelength ($I \approx A/\lambda^4$). So, the blue (shorter wavelength) end of the visible spectrum is scattered more strongly, giving the sky its characteristic color.

As shown in Figure 1, the process is called Raman scattering, if the energy of the scattered photon is different from that of the incident one (the process is referred to as Brillouin scattering when the phonon emitted or absorbed is acoustic, and Raman scattering when the phonon is optical) (inelastic scattering, second term of Equation (2)). As a result, light with frequencies ($\nu \pm \nu_i$), ($\nu \pm \nu_j$), ($\nu \pm \nu_k$) ... is emitted. In order that the total energy may be conserved, the vibrational energy of the sample is changed. If the irradiated molecule gains energy, the scattered lines in the Raman spectrum are at ($\nu - \nu_i$) and are called "Stokes lines." If the sample loses energy, then the scattered lines are at larger frequencies than ν (at ($\nu + \nu_i$)) ... and are called "anti-Stokes lines."

Classical theory shows that a vibration is Raman active if the polarizability changes during the vibration, and the Stokes lines are always stronger than the anti-Stokes lines. (This latter fact is explained by quantum theory as a consequence of the Maxwell–Boltzmann distribution law.) In crystals, the photon wave vectors are small compared with the dimensions of the Brillouin zone; thus, the momentum conservation law can be obeyed only if the wave vectors of the scattered phonons are also very small (so only the zone center phonons participate in the Raman scattering). It is difficult to determine which of the phonons are Raman active, as

Figure 2. Stimulated Raman scattering: depletion at the pump frequency, and amplification of the Stokes beam.

changes of the components of the polarizability tensor are not obvious from inspection of the normal modes of vibration. Considering the symmetry of the molecule or the crystal and the polarization properties of the Raman lines, application of group theory gives a clear-cut solution to this problem (Poulet & Mathieu, 1970). If the polarization P contains terms of higher order (neglected in Equation (1)), these subsequent terms give hyper-Raman effects.

When the energy of the exciting line coincides with that of an allowed electronic transition of the compound, the intensity of the Raman spectra is enhanced and a series of overtones is observed—this mechanism is referred to as “resonance Raman scattering.” This technique has been used in solid state and biophysics studies to identify intrinsic localized modes (Swanson et al., 1999).

Stimulated Raman scattering (SRS) is a nonlinear process in which a medium is irradiated by an intense laser beam at ν_p (pump frequency) and by a weaker beam at ν_s (Stokes frequency). The frequency spacing $\nu_p - \nu_s$ corresponds to a Raman frequency of the medium. In the simpler case, SRS amplifies the weak Stokes beam and depletes the pump beam (Raymer & Walmsley, 1991; see Figure 2).

A Raman soliton has been predicted (Chu & Scott, 1975) as a solution of the equations for transient SRS, and an experimental observation of transient SRS in H_2 gas was reported (Drühl et al., 1983). Recently, a complete interpretation of the above experiment has been given (Claude et al., 1995). The Raman soliton is still to be observed.

Picosecond time-resolved coherent anti-Stokes Raman spectroscopy (CARS) is a method for studying vibrational dephasing in the time domain. It is a special case of four-wave mixing (Levenson, 1982). Two intense simultaneous pulses at ν_p (pump) and ν_s (Stokes) specifically excite each Raman active mode at $\nu_p - \nu_s$. The third beam (probe pulse), also at the frequency ν_p , is delayed by the variable time t and stimulates coherent anti-Stokes emission. This technique is used to study the vibrational lifetime in anharmonic crystals and biomolecules to identify breathers excitations (Kosic et al., 1984).

Infrared (IR) absorption occurs when a compound is irradiated with frequencies that match its natural vibrational (or rotational) modes (Nakamoto, 1986). Absorption spectra in the infrared region originate in transitions between two vibrational levels of a sample in the electronic ground state. The absorption intensity depends on the change in dipole moment that occurs as a result of molecular vibration. If a molecule at equilibrium has a center of symmetry, the vibrations for which the center of symmetry is shared will be infrared inactive. Symmetry selection rules allow prediction of infrared activity when the associated normal coordinate belongs to the same species as one of the components of the dipole moment. When internal vibrations are coupled with phonons, nonlinear characters are observed in the infrared absorption bands: splitting, corresponding to the creation of a vibrational polaron or breather, intensity strongly dependent on the temperature, or an unusual number of overtones (Careri et al., 1984; Barthes et al., 2002). Time-resolved IR spectroscopy is of crucial importance in this field (Hamm et al., 1998; Xie et al., 2000).

RAYLEIGH-BÉNARD CONVECTION

See Thermal convection

RAYLEIGH-TAYLOR INSTABILITY

The Rayleigh-Taylor instability arises when a layer of heavy fluid is accelerated into a lighter one. This occurs, for instance, if a heavy fluid is put on top of a lighter one in a uniform gravity field. Under these unstable conditions, small disturbances of the interface between the two layers grow, at first exponentially with a growth rate proportional to $\sqrt{k}$ where k is the wave number, as long as the perturbation is small compared with the wavelength. The subsequent nonlinear growth has been mostly investigated numerically or experimentally. The Rayleigh-Taylor instability was first discovered by Lord Rayleigh (John William Strutt) in 1883 for the gravitational case and then extended to the case of any accelerating fluid by Geoffrey Taylor in 1950.

One of Taylor's major observation is related to the Manhattan Project (September 1942 to January 1945), which ultimately led to the successful development of atomic bombs. Indeed, in May 1944, when he was invited to join the project, Taylor pointed out problems due to implosion instabilities (especially of the Rayleigh-Taylor type). This led to a very conservative design to minimize possible instabilities. At the same time, James Tuck brought the idea of explosive lenses for detonation wave shaping, suggesting the use of three-dimensional (3-d) lenses to create a spherical implosion and reduce instabilities.

To study an example of the Rayleigh-Taylor instability, let us look at the interface between a heavy

fluid of density ρ_2 on top of a lighter fluid of density ρ_1 subject to gravity. The interface is assumed to be horizontal and both fluids are assumed to be at rest initially. For simplicity, we look at the two-dimensional case. We wish to show that a small disturbance of the interface will grow exponentially fast. Indeed, a small disturbance can engender small potential velocities $v_1 = -\nabla\phi_1$ and $v_2 = -\nabla\phi_2$ in the lower and upper fluid respectively, such that

$$\phi_2 = Ae^{-ky+nt} \cos(kx), \quad (1)$$

$$\phi_1 = -Ae^{ky+nt} \cos(kx). \quad (2)$$

Then the interface that is given by the equation $y = \eta(t, x)$ satisfies $\partial_t \eta = -\partial_y \phi_1(y=0) = -\partial_y \phi_1(y=0)$. Hence,

$$\eta = \frac{Ak}{n} e^{nt} \cos(kx). \quad (3)$$

Neglecting the nonlinear term, the Euler equation reads $-\rho_2 \partial_t \nabla \phi_2 + \nabla p_2 = -\rho_2 g \mathbf{j}$, which yields

$$p_2 = p - \rho_2 g y + n \rho_2 \phi_2, \quad (4)$$

where p is the mean pressure at the interface. Similarly, the pressure in the lower fluid is given by

$$p_1 = p - \rho_1 g y + n \rho_1 \phi_1. \quad (5)$$

At the interface, the pressure should be continuous, namely, $p_1 = p_2$ and, hence,

$$(\rho_2 - \rho_1)g\eta = n(\rho_2 + \rho_1)Ae^{nt} \cos(kx). \quad (6)$$

Combining (3) and (6), we get

$$n^2 = -kg \frac{(\rho_1 - \rho_2)}{(\rho_2 + \rho_1)}. \quad (7)$$

The Atwood number is defined by $At = (\rho_1 - \rho_2)/(\rho_2 + \rho_1)$. In the case $\rho_2 > \rho_1$ (heavy fluid on top of lighter fluid), $-1 < At < 0$, and

$$n = \pm \sqrt{-At kg}. \quad (8)$$

The unstable mode corresponds to $n = \sqrt{-At kg}$ and yields exponential growth as long as the nonlinear terms can be neglected, namely, as long as η is small compared with the wavelength. In experiments, surface tension and viscosity have a regularizing effect on the motion by damping the waves with large wave numbers. Indeed, for small Weber (and/or) large Reynolds numbers, the Rayleigh-Taylor instability has a short-wave character due to a balance between the exponential growth and the viscous or the surface tension effect, and hence, there exists a wave number that has a maximum growth rate. This is similar to the Rayleigh number, which represents the ratio of the destabilizing effect of buoyancy to the stabilizing effect of viscous force in the Rayleigh-Bénard instability.

Experiments and numerical simulations have given much insight into the different stages of the instability formation. However, they have yielded few quantitative results. Different numerical methods have been used such as the 3-d front tracking and the lattice Boltzmann method. In all cases, the geometric complexity of the interface is a source of difficulties for most of the algorithms. As explained in Sharp (1984), we can divide the growth of the instability into four stages. In the first, we have an exponential growth that can be quantitatively computed using the linear perturbation theory, which is no longer valid if the amplitude is about 20% of its wavelength. During the second stage, the perturbation grows nonlinearly to form bubbles of light fluid rising into the heavy one and spikes of heavy fluid falling into the light one. This stage is strongly influenced by the three-dimensional effects. Experiments and numerical simulations have shown that the bubbles rise at an approximately constant velocity during this stage. The third stage is characterized by the development of additional structures on the spikes. Moreover, the Kelvin–Helmholtz instability begins to develop due to the jump in the tangential velocity at the interface between the two fluids. The heavy fluid begins to roll up along the sides of the spikes to form “mushrooms.” This phenomenon is more pronounced when the Atwood number is small and is a 3-d phenomenon. Eventually, the flow evolves into turbulent or chaotic mixing, which dominates the fourth stage.

In engineering applications, the Rayleigh–Taylor instability plays an important role in inertial confinement fusion (ICF). It is also present in the extraction of oil. Indeed, to extract oil from the Earth, water is accelerated into oil, and since oil is lighter, the interface presents the Rayleigh–Taylor instability. Some of the engineering solutions consist in adding polymers to the water. Moreover, there are many astrophysical and geophysical objects that present the Rayleigh–Taylor instability such as the supernova explosions, mantle convection, and deep convection in the ocean.

Another instability that is similar to the Rayleigh–Taylor one is the Richtmyer–Meshkov instability, which arises in the case of an impulsive or instant loading as opposed to a constant acceleration (such as gravity) in the Rayleigh–Taylor case. In many applications the situation is intermediate between these two limiting cases.

REACTION-DIFFUSION SYSTEMS

How did life appear and develop on Earth? Although there is not complete agreement, a convincing answer is that given the required conditions (which were almost surely satisfied billions of years ago), life spontaneously emerged through the endless battle of survival of the fittest from a primordial chemical soup. The theory of random catalytic networks (Kauffman, 1995) shows that autocatalytic reactions are likely in this context; thus, the theory of interactions between chemical reactions and molecular diffusion takes center stage in emergence of biological life from atoms and molecules in a system.

Today, reaction-diffusion systems have found many applications ranging from chemical and biological phenomena to medicine (physiology, diseases, etc.), genetics, physics, social science, finance, economics, weather prediction, astrophysics, and so on (Aronson & Weinberger, 1975; Grindrod, 1996; Murray, 2002; Scott, 2003). Even for phenomena that bear no initial resemblance to these processes, it is sometimes useful and productive to use the reaction-diffusion metaphor in order to gain insight into their dynamics.

An important contribution to this subject comes from the theory of pattern formation in nature. Many physical phenomena giving rise to natural patterns can be understood in terms of the interaction of a short-range self-enhancing reaction and a long-range antagonistic reaction. Take a fire, for example. It is a self-enhancing process: more heat is released as more fuel is burned. In the process oxygen and fuel which act as antagonistic factors are consumed and this may lead to a fire's extinction if fuel is not replenished. Also, the heat produced is transported from its local source through diffusion. Thus, we have the two main ingredients for pattern formation, namely, a local antagonistic interaction between two species (or reactions) coupled with a means of transport of their products. Historically, this is also one of the first examples of reaction-diffusion systems studied scientifically, for obvious reasons given the necessity for improved heating and lighting at the beginning of the industrial age. In his “Christmas Lectures” at the Royal Society in London, Michael Faraday discussed the importance

of understanding the candle flame and its analogy with the process of respiration of biological organisms (Faraday, 1861). The flame of the candle is an archetypal nonlinear reaction-diffusion system that today, after decades of research, provides a basis for the science of combustion. In this article, we review the essential topics in the field of reaction-diffusion systems from a theoretical point of view and also consider some of their numerous applications.

Theoretical Aspects

A reaction-diffusion (RD) equation is typically obtained by combining Fick's law of diffusion with the chemical reaction rate law. Although the theory can be made rigorous by using the theory of stochastic differential equations leading to the Fokker-Planck equation (Øksendal, 2003), we present here a heuristic argument. If we consider for simplicity a small domain interval on the line inside which we have a concentration c of some reacting species, then the diffusive flux J_{in} of c into one side of the small region will depend on the concentration gradient, $\partial c / \partial x$, at that boundary and the diffusion coefficient, D , with $J_{\text{in}} = -D(\partial c / \partial x)_{\text{in}}$. The parameter $D > 0$ is called diffusivity with physical units of m^2/s . The diffusive flux out of the region at the other side J_{out} will similarly be given by $J_{\text{out}} = -D(\partial c / \partial x)_{\text{out}}$, where the concentration gradient is now evaluated at the other boundary. The rate at which the concentration grows due to diffusion then depends on the difference between these two fluxes—and so involves the second derivative $\partial^2 c / \partial x^2$. If we add a kinetic reaction rate term $r(c)$, then the reaction-diffusion equation, which gives the rate of change of the concentration c in time at any spatial point, has the general form

$$\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial x^2} + r(c). \quad (1)$$

This can be extended to any number of spatial variables to read

$$\frac{\partial c}{\partial t} = D \Delta c + Q(x, t, c, \dots), \quad (2)$$

where Δ denotes the n -Laplacian ($1 \leq n \leq 3$) and Q accounts for other influences including sources or sink terms. Other more complicated formulations for the flux terms are possible in diffusive processes; see Okubo & Levin (2001) for an account of these ideas in biology. In many sciences, the motion of particles or living organisms is subjected to both internal and external effects often acting simultaneously. For example, in biology, bacteria are known to move randomly (akin to diffusion) but are also able to follow a chemical gradient (chemotaxis). Mathematically, this leads to a description involving reaction-diffusion-chemotaxis equations. For example, chemical attractant

signaling can give rise to spiral wave pattern formation at a certain life stage in colonies of the slime mold *Dictyostelium discoideum*. Other extensions include advection, electric and/or magnetic field effects, and so on. In many of these cases, the resulting mathematical description is far more complicated than the simple RD systems above and, for many situations, their exact formulation is still an open question.

In writing an equation such as (2), we will consider that c is a vector; thus, Equation (2) will describe a system of RD equations. A simple archetypal example for a RD system is a quadratic autocatalytic reaction between two chemicals according to the rule $A + B \rightarrow 2B$ with rate $r = kab$. Denoting by a the concentration of A and by b that of B, the two species satisfy (after suitable scaling) the equations:

$$\begin{aligned} \frac{\partial a}{\partial t} &= D_1 \Delta a - ab, \\ \frac{\partial b}{\partial t} &= D_2 \Delta b + ab. \end{aligned} \quad (3)$$

From a mathematical point of view, systems of equations such as (3) must be well posed in order to exhibit appropriate solutions. To specify the problem, let the state variables $c(x, t), \dots$ represent the density or concentration of some substance at time $t \geq 0$ and position x in R^n . Then Δc denotes the Laplacian of c with respect to the space variable x , and Equation (1) is an example of a parabolic equation of evolution. If (1) holds for all x in R^n , then the problem is fully specified once appropriate initial conditions

$$c(x, 0) = c_0(x) \quad (4)$$

are known. If (1) holds in a limited domain $\Omega \subset R^n$, then we must impose boundary conditions on c at $\partial\Omega$ (the domain boundary) compatible with the physical situation. Neumann (or no-flux), Dirichlet, or Robin conditions are usually employed in applications. Although these are linear conditions on the variable c , nonlinear conditions could also be applied. The above system of differential equations with specified initial and boundary conditions is called an initial value problem or IVP in short.

For an IVP, one naturally asks whether there are solutions. In the case of reaction-diffusion systems, there are two different aspects to consider; local existence and global existence of the solutions. By local existence we mean the existence of the solutions over a short time interval. Global existence properties are exhibited by the solutions of the IVP when they are known to exist for all positive time. In some applications global existence is precluded because the solution exhibits blow-up in finite time. This means that there is (x_0, t_0) such that $c(x, t) \rightarrow \infty$ as $(x, t) \rightarrow (x_0, t_0)$. These questions are difficult to deal with in general for RD systems although there is a well-developed body

of results available in the literature (Grindrod, 1996). Moreover, even if the existence of a particular type of solution is established, further important theoretical questions involve the uniqueness of the solution and the stability of this solution to small perturbations. To approach these questions, one usually transforms the given system of RD equations

$$\frac{\partial c}{\partial t} = D\Delta c + f(x, t, c, \nabla c) \tag{5}$$

into a differential equation in an abstract Banach space (for example, $L^2[\Omega]$) as in

$$c_t + Ac = f, \quad t > 0, \quad c = c_0 \quad \text{at } t = 0. \tag{6}$$

Then, the above questions reduce the problem to studying the properties of the (linear) operator A , which are mainly resolved if one knows its spectrum. However, in practice this is a difficult question as A has an infinite-dimensional spectrum.

For many RD systems of interest, in practice, there are several rather specific and powerful analytical methods that give detailed insights into the solutions, including comparison principles, invariant regions, matched asymptotic expansions, nonlinear bifurcation, group invariant symmetries, and so on (Grindrod, 1996).

Applications of Reaction-Diffusion Systems

Historically, some of the first applications of reaction-diffusion equations were in population dynamics, combustion, and nerve impulse conduction. Thus, one of the simplest reaction-diffusion equations is the Fisher–KPP equation

$$\frac{\partial u}{\partial t} = D\Delta u + f(u), \tag{7}$$

which was proposed independently by Ronald Fisher (1937) and Andrei Kolmogorov, Ivan Petrovsky and N. Piscounoff (1937) to explain the spread of genetic influences. In those papers a quadratic function of the form

$$f(u) = ku(1 - u) \tag{8}$$

was used with $k > 0$ a parameter. A year later, Yakov Zeldovich and David Frank-Kamenetsky used the same equation but with f being a cubic polynomial as a model that represented flame front propagation (Zeldovich & Frank-Kamenetsky, 1938). Due to its generic form, Equation (7) soon found new interesting applications, for example, as a model of impulse conduction along an active nerve fiber, with the solution $u(x, t)$ representing the voltage across a cell membrane.

An important class of similarity solutions in the form of traveling waves (TW) is common to both the RD system (3) (and many of the type at (5)) and scalar equation (7). A traveling wave is a solution of the form $u(x, t) = u(x - vt) = u(y)$, where $y = x - vt$ is the traveling-wave coordinate with v being the wave

Figure 1. Typical concentration profiles for solutions a, b obtained by numerically solving the RD system (3).

speed. The problem is simplified because in the TW coordinate we have now to solve an ordinary differential equation (rather than a partial differential equation). For example, (7) generates the following TW equation to solve

$$\frac{d^2u}{dy^2} + v\frac{du}{dy} + f(u) = 0, \tag{9}$$

which must be supplemented with appropriate boundary conditions as $|y| \rightarrow \infty$.

Propagating waves are an important dynamical feature of many physical systems, hence, TW problems have been carefully studied. Key mathematical questions in these cases are the existence and possibly uniqueness of the waves. After the existence of a TW solution is established, it is of physical significance to study its stability under perturbations. Other questions are the influence of the initial conditions on the selection of a particular type of TW solution and the study of the shape of the TW solution. An extensive theory for TW solutions has been developed that deals with many interesting classes of RD systems (see Volpert et al., 1994; Grindrod, 1996; Scott, 2003). One particularly striking property of TW solutions for RD equations such as (3) or (7) is the existence of either a unique speed or a semi-infinite spectrum of speeds with a positive threshold boundary. The first case corresponds to a cubic nonlinearity, as in the nerve conduction application above, whereas the latter applies to a quadratic nonlinearity. These features can be contrasted with the paradox of infinite speed behavior exhibited by the classical diffusion equation. For example, with the quadratic form (8), Equation (7) has a TW solution for all $v \geq v_0 = 2\sqrt{kD}$. A similar property applies to system (3) although in practice only for a limited class of RD equations is an analytical expression known for v_0 . In Figure 1, we show a typical profile of a TW solution to system (3) obtained from numerical simulations on a semi-infinite one-dimensional spatial domain via an implicit finite-difference scheme.

One of the oldest but still active fields of application is the modeling of nerve impulse conduction along a

Figure 2. A full-sized action potential and an unstable threshold impulse for the HH axon: (Courtesy of A.C. Scott.)

responsive fiber (Scott, 2003). In 1952, Alan Hodgkin and Andrew Huxley formulated a detailed description of the dynamics of membrane ionic current for a dozen giant squid axons (Hodgkin & Huxley, 1952). They produced the following differential system describing the dynamics of the voltage $V(x, t)$ across the nervous cell (assumed one-dimensional):

$$rc_a \frac{\partial V}{\partial t} = \frac{\partial^2 V}{\partial x^2} + rj_i, \quad (10a)$$

where

$$j_i = 2\pi a J_i, \quad J_i = G_K n^4 (V - V_K) + G_{Na} m^3 h (V - V_{Na}) + G_L (V - V_L). \quad (10b)$$

Here, a is the radius of the fiber, r is the longitudinal resistance per unit length of the fiber, c_a is the membrane capacitance per unit length, and j_i is the total ionic current flowing across the membrane per unit length. The expressions appearing in Equation (10b) are given in terms of differential first-order rate equations describing the concentrations of potassium, sodium “turn-on” and “turn-off” variables (n , m , and h). These equations are determined from experimental data. The RD system (10a, 10b) is now known as the Hodgkin–Huxley (HH) system. Using TW theory, one can show that HH is an excitable RD system for parameter ranges of interest that admit traveling pulse solutions called action potentials (see Figure 2).

From a theoretical perspective, the HH system is complicated; thus, simplified theoretical models have been proposed to capture qualitative features. One such model is the system proposed by FitzHugh and Nagumo (FitzHugh, 1961), which reads

$$\frac{\partial V}{\partial t} = \frac{\partial^2 V}{\partial x^2} + F(V) + R, \quad \frac{\partial R}{\partial t} = \varepsilon(V - c_a - b_a R), \quad (11)$$

Figure 3. A computer generated scroll wave. (Courtesy of A. Winfree.)

where R is the slowly changing recovery variable and F has a cubic shape. The FitzHugh–Nagumo system admits periodic traveling waves and pulses both stable and unstable. In 2 or 3 spatial dimensions, target (ring) and spiral waves have been numerically produced that today are known to be characteristic types of TW solutions of an excitable system (Scott, 2003).

The most striking illustrations of target and spiral waves can be seen in excitable chemical reactions. Historically, the first such demonstration was produced in the chemical medium proposed by Belousov and Zhabotinsky, now known as the BZ reaction (Zhabotinsky, 1991). A dynamical system is called excitable when it responds in a qualitatively different way to perturbations that are below and above some threshold value, above which it typically amplifies those perturbations. After a pulse has been generated, the system takes some time (refractory state) until it can again support an impulse. In two dimensions, one can find target (ring) and spiral waves as in a typical BZ experiment (See photo in **Belousov–Zhabotinsky reaction** and also in color plate section).

To describe these solutions analytically, one can use a simplified model of the BZ reaction, such as the two-species Oregonator model developed by Field and Noyes (1974):

$$\begin{aligned} \varepsilon \frac{\partial a}{\partial t} &= \varepsilon^2 \Delta a + a(1 - a) - f \frac{a - q}{a + q} b, \\ \frac{\partial b}{\partial t} &= \varepsilon \Delta b + b - a, \end{aligned} \quad (12)$$

where ε , f , q are kinetics parameters related to the reagents rate reactions and a , b are proportional with the concentrations of HBrO_2 and a metal ion. Here the diffusion operator Δ denotes one-, two-, or three-dimensional diffusion. In the latter case, more complicated patterns are found such as toroidal scroll waves and multi-armed spiral waves. Figure 3 shows a computer generated scroll ring obtained in a model of the BZ reaction, which has also been observed experimentally.

To understand such solutions a geometrical theory of traveling waves propagating on arbitrary two- and

three-dimensional manifolds was developed by Tyson, Keener, Grindrod, and others around the mid-1980s, (see Grindrod, 1996). The idea is to compare the problem of three-dimensional wave propagation with that for wave propagation in one dimension. Consider the equation

$$\varepsilon \frac{\partial u}{\partial t} = \varepsilon^2 \Delta u + f(u), \tag{13}$$

which is in the Oregonator model of the BZ reaction (see Equation (12)). Suppose that u_1, u_2 are two solutions to $f(u) = 0$ and that (13) has a TW solution of the form $u = u(y)$ where $y = (x - vt)/\varepsilon$, so that

$$u'' + vu' + f(u) = 0 \tag{14}$$

satisfying $u \rightarrow u_1$ as $y \rightarrow \infty$ and $u \rightarrow u_2$ as $y \rightarrow -\infty$ for some speed $v > 0$. For a TW structure to exist in three dimensions, there should be an oriented surface M moving through R^3 such that $u \sim u_1$ ahead of the surface and $u \sim u_2$ behind it. Introducing a normal stretched variable depending on a curvilinear system of coordinates, one can show that a solution $u = \phi(\xi)$ exists subject to $\phi \rightarrow u_1$ as $\xi \rightarrow \infty$ and $\phi \rightarrow u_2$ as $\xi \rightarrow -\infty$ if and only if ϕ satisfies the TW equation

$$\phi_{\xi\xi} + (N + \varepsilon K)\phi_{\xi} + f(\phi) = 0. \tag{15}$$

From (14) and (15) we find that $u = \phi(\xi)$ is the inner solution of the problem when

$$v = N + \varepsilon K, \tag{16}$$

which is called the eikonal equation (Grindrod, 1996). Here N denotes the normal velocity, and K is twice the mean curvature of M . For example for circular waves, the speed of the curved wave v should be smaller than that of the planar wave v_0 . The eikonal equation gives $v = v_0 - 2D/r$, where r is the radius and D is the diffusion coefficient. Hence we have a condition for the initiation of circular waves that is purely geometric, namely, $r_{\text{crit}} = 2D/v_0$ for the critical radius of wave initiation. When two circular waves collide, they create cusp-shaped regions with positive curvature. The theory can also be applied to armed spirals and toroidal scroll waves (Grindrod, 1996).

Spiral waves generated by reaction-diffusion processes also occur in surface reactions as tiny spiral waves, visible only through a microscope, that form out of catalytic nitric oxide reduction by hydrogen on rhodium or platinum surfaces. Such pattern formation in surface reactions can be imaged by photoemission electron microscopy (PEEM).

Flames on a spinning disk have been studied at NASA where it is shown that target and spiral waves appear in a mixture of butane in He-O₂. A simple such model is the Salnikov RD system (Scott et al., 1997):

$$a_t = \nabla^2 a + \mu - a f(b), \tag{17a}$$

$$b_t = Le \nabla^2 b + \frac{1}{\kappa} (a f(b) - b). \tag{17b}$$

Figure 4. A spiral galaxy in Centaurus. VLT, European Southern Observatory.

Here $f(b) = \exp[b/(1 + \gamma b)]$ and $Le, \mu, \kappa, \gamma > 0$ are physical parameters with $\kappa \ll 1$.

Spiral forms are omnipresent throughout the visible and invisible universe in galaxies, accretion disks around black holes, coalescing interstellar clouds, and many other forms of matter and energy (see Figure 4). Lee Smolin (1996) has suggested that the formation of some spiral galaxies can be regarded as an RD process, and he produced a theory of cosmos as a self-sufficient organically developing natural system. In this scenario the galactic spirals (and everything inside them) are gargantuan relatives of the BZ waves.

Waves of spreading depression appear as electrochemical waves associated with the depolarization of the neuronal membrane of the brain as they spiral around lesions of the cortex. There is speculation that this wave activity is linked to epilepsy. Since Art Winfree's pioneering work, scroll waves have been linked quite firmly with cardiac arrhythmias (Keener & Sneyd, 2002). In particular, the onset of fibrillation seems to be connected with the development of scroll type waves (high-frequency waves of electrical activation that recirculate repeatedly, preventing normal function) in the heart muscle. In this case, the heart contractions are much smaller in amplitude than the normal coordinated contraction and also aperiodic, which has potentially fatal consequences.

In early embryo development, circular calcium waves propagate and occasionally annihilate on the surface of a fertilized egg cell as a precursor to cell division. However, in frog eggs they take the form of spiral waves whose purpose is still unclear.

The dynamics of biological populations can self-organize in propagating traveling structures akin to

RD waves (Okubo & Levin, 2001). This is a classical topic in ecology with ramifications for studies in biodiversity. Among the pioneers of the field were Alfred Lotka in 1910 (Lotka, 1925) and Vito Volterra (1926), who have shown that equations similar to those describing reacting chemicals can provide a crude description of interactions between a predator population and its multiplying prey population. Thus, Lotka–Volterra RD type interactions are the heart of modeling in much of ecological dynamics and modeling of epidemics. The spatial spread of epidemics can be usefully approached with a “prey–predator” type dynamics involving the three species: S (the susceptibles), I (infectives), and R (removed individuals) in a population (Kermack & McKendrick 1932; Murray, 2002):

$$\begin{aligned} S_t &= -\beta IS, & I_t &= \beta IS - \gamma I + D \Delta I, \\ R_t &= \gamma I. \end{aligned} \quad (18)$$
